We survey, in a partial way, multi-scale approaches for the modelling of rubber-like and soft tissues and compare them with classical macroscopic phenomenological models. Our aim is to show how it is possible to obtain practical mathematical models for the mechanical behaviour of these materials incorporating mesoscopic (network scale) information. Multi-scale approaches are crucial for the theoretical comprehension and prediction of the complex mechanical response of these materials. Moreover, such models are fundamental in the perspective of the design, through manipulation at the micro- and nano-scales, of new polymeric and bioinspired materials with exceptional macroscopic properties.

## 1. Introduction

The mechanical properties of rubber-like materials have been offering an outstanding challenge to the solid mechanics community for a long time. The behaviour of such materials is quite difficult to predict because rubber self-organizes into mesoscopic physical structures that play a prominent role in determining their complex, history-dependent and strongly nonlinear response.

In the first chapter of the celebrated book by Treloar [1] on the physics of rubber elasticity, we find an interesting

implicit definition of a rubber-like material based on three simple requirements [1, p. 11]:

- (1) the presence of long-chain molecules, with freely rotating links;
- (2) weak secondary forces between the molecules; and
- (3) an interlocking of the molecules at a few places along their length to form a three-dimensional network.

The Treloar *cartoon* of the molecular structure of rubber represents a guideline to develop basic models of amorphous rubber-like materials and soft tissues. Indeed, requirements (1) and (2) are the basic assumptions of the so-called entropic theory of elasticity, and requirement (3) is equivalent to postulate the existence of a coherent solid network in which the molecules are linked together and do not move independently. We point out that these requirements are shared with several biological and bioinspired materials. In the last decades, theoretical developments in these fields have been strongly linked to the search of phenomenological macroscopic models, of multi-scale material models, and to the techniques required to design new high-performance polymeric and bioinspired materials [2–4].

Around 1930, *molecular* models were introduced to describe the mechanical behaviour of natural rubber, in order to deduce quantitative thermodynamical models based on the three requirements recalled above [5,6]. Around the same time the German engineer Heinrich Hencky was conducting some experiments on rubber belts furnished by the Goodyear Tire and Rubber Company to the Massachusetts Institute of Technology. He then proposed a phenomenological generalization of the classical linear theory of elasticity to cope with finite deformations via the introduction of the *Hencky strain measure* [7].

All these models have been unsuccessful for a general and proper treatment of the large deformation regime. Only with the celebrated Mooney paper in 1940 [8] and the following systematic investigations by Rivlin [9] do we encounter more actual phenomenological treatments of the mechanics of finite deformations of rubber-like materials. Truesdell & Noll's *Handbuch* ([10], p. 118) recalls this period as follows:

We recall that at the beginning of the XIX century the knowledge of the classical theory of finite elasticity was based on 'applied' papers often proposing 'new' theories all either pointlessly special or wrong. Mainly only in Italy, due to the teaching and writing of Antonio Signorini, the correct approach to nonlinear elasticity was pursued, though little advanced.

Later on, the advancements of the mechanical theory of rubber-like materials proceeded by following a twin-track approach, based on one hand, on the development of non-Gaussian statistical or molecular theories and on the other hand, on the development of phenomenological constitutive models in continuum mechanics. Often the statistical method gave a deeper and more consistent insight into the molecular structure of rubber-like materials, whereas the continuum mechanics models were more successful in the representation of the macroscopic experimental behaviour. The dichotomy statistical versus continuum mechanics is exemplified by the necessity of the so-called  $C_2$  *energy term*, pointing to the necessity of a synergic approach between the phenomenological and the statistical methods.

To summarize the related long-lasting debate, we recall that the classical Gaussian approach of statistical mechanics for rubber allows us to deduce analytically the well-known simple neo-Hookean model. This very special model, which was fundamental for its analytic simplicity in the understanding of many theoretical aspects of nonlinear elasticity theory, is satisfactory in the description of the macroscopic mechanical behaviour of rubber elasticity only under specific assumptions. Indeed, it was shown [11] that the neo-Hookean model is able to describe the experimental behaviour of rubber only for small and moderate shear deformations. On the contrary, the phenomenological Mooney–Rivlin constitutive theory, by complementing the neo-Hookean model with the so-called  $C_2$  term, delivers a simple solution to the above-mentioned

limits. As a result, while *Mooney theory does not provide a satisfactory and self-consistent basis for the representation of the properties of rubber in the most general state of strain* [1, p. 99], the confrontation of its predictions with the experimental data show that this model is significantly more predictive than the neo-Hookean model.

This *scenario* opened a discussion on the reason for the *discordances* between the experimental behaviour and the statistical theory results (see [12] for an initial comment in this direction). Treloar [1] provides five possible reasons to understand the *molecular significance of the deviation from statistical theory* [1, p. 227]

- (1) non-Gaussian effects both for the chains and the network;
- (2) internal energy effects;
- (3) chain entanglements;
- (4) irreversible effects; and
- (5) non-random packing effects.

Today, many fundamental steps to solve these issues have been made and this crucial evolution has been at the root of a radical overhaul of the dichotomy recalled above. In particular, the application of nonlinear elasticity theory to the framework of biomechanics of soft tissues provided a new impetus for a synergetic approach between the statistical mechanics and the continuum mechanics theories. This synergy opened the path to a new generation of models [13–17] relating the macroscopic response to the material properties at lower scales. The complexity and the technological and scientific impact lead to a variety of new proposed multi-scale approaches especially in the case of nano-scale elaborated materials (e.g. [18] for a review related to nano-composite polymers). In this fundamental evolution, we must not underestimate the crucial role of both experimental material mechanics and numerical analysis. The evolution in experimental expertise allows the comprehension of the behaviour at the network and single polymeric molecule scales (e.g. [17,19] and references therein). On the other hand, numerical methods gave a strong impulse both for the analysis of the micro- and nano-scale behaviour (e.g. molecular dynamics, Monte Carlo and Brownian dynamics approaches [18]) and of the macroscopic strongly nonlinear differential evolutive problems (e.g. [20] and references therein).

The aim of this review is to provide an overview of this research activity. It is important to remark that we are not aiming at *any* completeness on the immense literature on the multi-scale modelling of rubber-like and soft materials (e.g. [20–25]). Instead our discussion will be focused on the meso-macro scale passage, where the results have been shown to be efficient in the description of many phenomena, fundamental in technological applications, such as damage, residual stretches, healing, hysteresis. We are only considering some explicit examples showing the possibility of deriving three-dimensional macroscopic models starting from the material properties at lower scales. This possibility is fundamental not only to predict the mechanical behaviour of these materials, but also to design new rubber-like and bioinspired materials based on the growing ability of manipulating them at the lowest scales. Fully multi-scale approaches may be imagined to be derived by sequential multi-scale passages, deducing the material properties at each scale by the properties of the previous lower scale (see again [18] for a review).

The plan of the paper is the following. The next section is devoted to recalling basic equations and some fundamental aspects of the theory of nonlinear elasticity related to the modelling of rubber-like materials (clearly this section is not an introduction to nonlinear elasticity and we assume that our readers are already familiar with this framework [10,26]). In §3, we introduce the Gent model and other similar models and we explain how this simple model is related to the molecular character of the polymeric network. Section 4 is devoted to the *micro–macro* passage. Section 5 is a collection of some important results of the last few years. The last section is devoted to concluding remarks.

## 2. Basic equations

Rubber-like materials are typically characterized by the ability of undergoing very large reversible deformation. As a consequence they can be modelled (at least for a certain range of deformation, temperature and time scales) as hyperelastic materials. We now recall some basic results of the nonlinear theory of elasticity to fix the notation and give a rigorous and quantitative description of some of the previous comments.

Let us consider the deformation of a body  $\Omega$ ,  $\Omega \ni X \mapsto x = x(X)$  and let  $F = \text{Grad}(x)$  be its gradient. Let  $B = FF^T$  be the left Cauchy–Green deformation tensor and let

$$I_1 = \text{tr}(B), \quad I_2 = \frac{(I_1^2 - \text{tr}(B^2))}{2} \quad \text{and} \quad I_3 = \det B$$

be its principal invariants. If a material is hyperelastic and isotropic [11], we may introduce a strain-energy density function  $W = W(I_1, I_2, I_3)$ .

The usual moduli of the theory of linear elasticity, such as the tensile modulus or the bulk modulus, may be deduced in the limit of infinitesimal deformations. Because the modulus of bulk compression of rubber is quite high with respect to its tensile modulus, it is usual to treat rubber as incompressible. In this case, only isochoric deformations are admissible,  $I_3 = 1$ , and  $W = W(I_1, I_2)$  only.

In this setting, the Cauchy stress tensor  $T$  is given by the representation formula

$$T = -pI + 2 \frac{\partial W}{\partial I_1} B - 2 \frac{\partial W}{\partial I_2} B^{-1}, \quad (2.1)$$

where  $p$  is the Lagrange multiplier associated with the constraint of incompressibility. Moreover, in the absence of body forces, the equilibrium equation is

$$\text{div } T = 0, \quad (2.2)$$

where  $\text{div}$  is the divergence operator with respect to  $x$ .

The *basic problem* in this framework is the determination of the functional form of the energy density  $W$ . It is interesting, by analysing the literature, to observe how scientists with different backgrounds face this problem from various angles and to show why a synergic contribution is crucial for a successful approach in this field. Typically, a mathematician is mainly interested in the understanding of the qualitative properties of the strain-energy functional to deduce the mathematical structure of the theory and the existence and regularity properties of the solutions. On the other hand, a material scientist could be interested only in having a mechanical model estimating and qualitatively describing the observed experimental phenomena. Finally, an engineer may be interested in simulations of mechanical devices and may be mainly focused on the possibility of quantitatively describing specific experimental data and of implementing numerically the model.

In this section, we are not interested in analysing the ability of a specific model to give a detailed description of the experimental data for a huge class of deformations. Instead, we are interested in presenting the ‘building bricks’ of the theories modelling the mechanical behaviour of rubber-like materials. A rational way to reach this goal is to analyse how different choices of the strain-energy function  $W$  induce so-called ‘universal’ properties of their mechanical behaviour, to be compared with the experimental ones.

The most *representative* strain-energy density function for the statistical theory of rubber-like materials is surely the neo-Hookean (single constant) model,

$$W = \frac{E}{6}(I_1 - 3), \quad (2.3)$$

where the small strain tensile modulus  $E$  can be related to molecular quantities (e.g. [1]).

Observe that the neo-Hookean model belongs to a particular class of materials where the energy density depends on the first invariant only (*generalized neo-Hookean materials*), i.e. such that  $W = W(I_1)$  only. On the other hand, the Mooney–Rivlin material does not belong to this class,

being described by the phenomenological constitutive equation

$$W = C_1(I_1 - 3) + C_2(I_2 - 3), \quad (2.4)$$

where  $C_1$  and  $C_2$  are two material constants whose mechanical meaning must be adjusted *a posteriori* to fit experimental data.

The strain energies (2.3) and (2.4) represent two particularly meaningful and simple prototypes of the various constitutive laws considered in the mechanical modelling of nonlinear incompressible elastic materials. Many other models have been proposed and a survey of these models can be found, for example, in Arruda & Boyce [14]. The variety, difference and number of the proposed models can be considered to give a measure of the uncertainty existing in the scientific literature about mechanical models for rubber-like materials.

### (a) The $C_2$ term

The corresponding *first* question to address is the possibility of providing a rational approach to analyse the  $C_2$  *voxata quaestio*. The mathematical problem is to test the *generalized neo-Hookean* hypothesis

$$W = W(I_1). \quad (2.5)$$

This is an important point because the molecular approach is usually associated with generalized neo-Hookean models. Rivlin and co-authors have proposed a detailed discussion about the  $C_2$  term [27] (see also [28,29]), based on a comparison with experimental data. Here we present a theoretical systematic approach that identifies rationally the right experiments showing the *falsifiability* of the  $\partial W/\partial I_2 = 0$  hypothesis. Specifically, Horgan & Saccomandi [30] and Wineman [31] have independently proposed to find out whether a strain energy of the form  $W = W(I_1)$  is a reasonable assumption by determining the existence of *universal relations*, i.e. equations that hold irrespective of the special form of  $W$ .

To illustrate explicitly this idea, let us consider the simple shear deformation

$$x = X + \kappa Y, \quad y = Y \quad \text{and} \quad z = Z, \quad (2.6)$$

where  $\kappa$  is a constant measuring the *amount* of shear. This deformation is probably the simplest example of finite deformation we can imagine, and we recall, as noted by Mooney in [8], that

[...] if the sample is sheared by a shearing stress, or traction, Hooke's law is obeyed over a very wide range in deformation.

Since as we now show, the proposed approach suggests that we find a discrepancy between simple shear data and a constitutive assumption of the form  $W = W(I_1)$ , then the root of this discrepancy can be considered *structural* because for simple shear, experimental data are easy to collect and compare with theoretical results.

In the case of (2.6) using (2.1), we obtain

$$\begin{aligned} T_{11} &= -p + 2(1 + \kappa^2)W_1 - 2W_2, & T_{12} &= 2\kappa(W_1 + W_2), & T_{13} &= T_{23} = 0, \\ T_{22} &= -p + 2W_1 - 2(1 + \kappa^2)W_2, & T_{33} &= -p + 2W_1 - 2W_2, \end{aligned}$$

where  $W_i = \partial W(I_1, I_2)/\partial I_i$ ,  $i = 1, 2$ . By these equations, we easily deduce the two trivial universal relations  $T_{13} = T_{23} = 0$  and the celebrated Rivlin universal relation

$$T_{11} - T_{22} = \kappa T_{12}. \quad (2.7)$$

This last universal relation can be considered a measure of the nonlinearity of the material behaviour because in the linear theory of elasticity we have  $T_{11} \equiv T_{22} = 0$ .

Consider then a cubic specimen and assume that the faces normal to the  $Z$ -direction are traction free so that  $T_{33} = 0$  and

$$p = 2W_1 - 2W_2.$$

We then deduce that

$$T_{11} = 2\kappa^2 W_1, \quad T_{12} = 2\kappa(W_1 + W_2), \quad T_{22} = -2\kappa^2 W_2 \quad \text{and} \quad T_{13} = T_{23} = T_{33} = 0.$$

Now we have three trivial universal relations  $T_{13} = T_{23} = T_{33} = 0$ , plus (2.7).

As a result, if we hypothesize that  $W = W(I_1)$  only, we obtain

$$T_{11} = 2\kappa^2 W_1, \quad T_{12} = 2\kappa W_1 \quad \text{and} \quad T_{22} = T_{13} = T_{23} = T_{33} = 0. \quad (2.8)$$

Hence we deduced the new trivial universal relation  $T_{22} = 0$ , peculiar to generalized neo-Hookean materials.

The experimental check of this new equation is quite simple. It is sufficient to drill a hole on the upper plate that we use to shear the material. Investigating whether the material stays flat ( $T_{22} = 0$ ) or not ( $T_{22} \neq 0$ ) in this hole (for example, using digital image correlation) gives a quantitative measure of the falsifiability of the hypothesis  $C_2 = 0$  [32].

We may then deduce that we need both invariants to derive a realistic constitutive equation. Observe that a similar argument may be used by considering the simple torsion experiment or the classical biaxial experiment. Of course, this simple example represents a prototype of the need for more general theories and for the contribution of modern continuum mechanics to extend the mechanical theories for rubber-like materials.

## (b) Crucial points

The Mooney–Rivlin constitutive assumption (2.4) delivers a good model for an elastic material in simple shear, but it is not satisfactory in other deformation classes. This statement is supported by the comparison of the prediction of the model with experimental data [1], but once again it is possible to give theoretical reasons that let us understand, in some sense *a priori*, the limits of such a model.

In this perspective, consider the following homogeneous deformation

$$x = \lambda^{-1/2} X + \kappa_1 Z, \quad y = \lambda^{-1/2} Y + \kappa_2 Z \quad \text{and} \quad z = \lambda Z \quad (2.9)$$

composed of a simple extension along the  $Z$ -direction and two shears along the orthogonal axes. In the linear theory, these three deformations are decoupled whereas they are coupled in nonlinear theory. In particular, with the Mooney–Rivlin model (2.4) the simple extension (described by the parameter  $\lambda$ ) is coupled to the shear deformations (with amounts  $\kappa_1$  and  $\kappa_2$ ), but the two shear deformations are decoupled one from another. This represents a very special situation indicating some of the limits of the Mooney–Rivlin model.

A major advancement in nonlinear elasticity modelling of rubber-like materials, after the pioneer approaches recalled above, was made with by the introduction of the Ogden model (see [11], the reprint of the original paper in [33] and the recent [34]). As pointed out by Treloar [1, p. 235]

the utility of the Ogden formulation must be judged by its ability to represent the experimental data for rubber under all possible types of strain, preferably (though this is not a primary requirement) with the use of a relatively small number of terms.

Indeed, the Ogden strain energy is one of the principal advances in the analysis of nonlinear elasticity: this model was the first form of the energy density that allowed the fitting of experimental data for a variety of deformation classes and a reasonable range of strains.

After the Ogden model, some important steps, in our opinion, represent further *breakthroughs* in the research field of nonlinear elasticity and constitutive modelling of rubber-like materials.

These milestones are the Ball existence theorem in nonlinear elasticity [35], the Gent model [36] and the Ericksen extensions of nonlinear elasticity to non-(rank-one)convex energies.

Ball's existence theorem [35] can be considered as a major advancement in the mathematical theory of nonlinear elasticity. Its assumptions can also be reframed in the framework of the so-called Truesdell *Hauptproblem* [37], i.e. the problem of what requirements have to be imposed on the functional form of the strain energy to ensure existence and well-posedness of the equations of nonlinear elasticity. In this respect, we point out that this approach has been theoretically questioned by J. L. Ericksen in [38] as follows:

My view is that the domain of constitutive equations may include subdomains that are, in principle, inaccessible to the experimentalist... For solids, it is trickier to formulate physically appropriate stability criteria, and thus to classify similarly the different parts of the domain of constitutive functions... We do not evade the problem by discarding 'unreasonable' constitutive equations... There is a simple, classical example which serves to illustrate my views, as well as some of the subtleties which are to be expected: the equilibrium theory of the van der Waals fluid. Here, by commonly accepted stability calculations, we infer that part of the domain is not accessible to experiment, part is easily accessible, and part is accessible only if sufficient care is taken to minimize disturbances... I merely propose adoption of the mathematician's criterion: the weaker the hypothesis, the better the theorem... Gradually, it has become clear that elasticity theory can predict effects that we do not commonly think of as being associated with the adjective 'elastic'. In such cases, we should, I think, let elasticity theory enter into free competition with other theories capable of describing the effect at hand...

Based on these considerations, Ericksen extended Ball existence requirements, for example, to non-(rank-one)convex energy functions [39]. This kind of assumptions may also be deduced from a multi-scale method, based on the Cauchy–Born hypothesis, for materials with a crystal microstructure [38]. This advance was fundamental to extend the mathematical framework of nonlinear elasticity to many material phenomena considered out of its range of applications. We refer, for example, to the pseudo- and quasi-elastic behaviours [40,41], and damage and deformation localizations observed also in the case of rubber-like materials [42].

To be more explicit in the linear theory of elasticity, in order to ensure a mathematical and physical meaning, we require that the quadratic form energy density is *positive definite*. Ball's results bring *analogous* restrictions (such as polyconvexity) upon the strain energy in the nonlinear case. Here we do not focus on these important mathematical aspects of the constitutive theories of rubber-like materials, but we want to point out that they are often completely bypassed by the material science and engineering communities working in the field.

As we recalled above, in our opinion, another fundamental step in the modelling of rubber-like materials is represented by the simple idea of the Gent constitutive law, which described phenomenologically the results of the multi-scale approach proposed by the Arruda–Boyce theory [43].

In that paper Arruda & Boyce [43] proposed a new multi-scale theory based on the methodological procedure in the classical three-chains models of Flory & Rehner [44]. Their paper lead to an important resurgence of interest in the non-Gaussian effects in the statistical mechanics derivation of the rubber-like models. The Arruda–Boyce model is based on:

- (1) the use of the inverse Langevin function<sup>1</sup> for the computation of the end-to-end distance for a single chain of the polymeric network;
- (2) the eight chain network structure (e.g. [13]) to perform the network average;
- (3) the *affine assumption* imposing the coincidence of the network chain stretches and macroscopic stretches.

<sup>1</sup>The Langevin function is a special function defined as the inverse of  $L(x) = \coth(x) - 1/x$ .

The advantage of such a model is that it contains few constitutive parameters and that those parameters are directly connected to the microscopic properties of the material. However, we point out that the Arruda–Boyce model is a generalized neo-Hookean model, so that we may extend the previous criticisms to this model (see [45], for a detailed comparison of this model with experimental data). Moreover, due to the involvement of the inverse Langevin function, even the analysis of simple homogeneous deformations can be quite complicated. Despite these drawbacks it is important to point out that the Arruda–Boyce model has been the catalyst of a renewed interest in the entropic theory of elasticity and in the connections between the phenomenological and the molecular theories of elasticity. As a clear example of the following advancement in this field, we may refer to the works by Göktepe & Miehe [20]. These authors, by extending the multi-scale statistically based approach of Govindjee & Simo [46], and using a classical additive hypothesis for the energy density (see Flory & Erman [47]), deduced a multi-scale constitutive law. Interestingly, their theory takes care of non-affinity effects and considers the anisotropic (Mullins type) damage effect due to the deformation-driven network chains reorientation.

Another important point in the nonlinear theory of elasticity that we want to stress in this section is the determination of the constitutive parameters by fitting the experimental data. We remark that this important step, often underestimated, may represent a crucial drawback of the models, and this problem is sheared by both the phenomenological and molecular approaches. Indeed, due to the amorphous character of rubber-like materials, molecular theories need the introduction of *ad hoc* phenomenological assumptions. Therefore, some of the constitutive parameters in the framework of statistical mechanics cannot be obtained directly by *ab initio* considerations. As pointed out in [48], the major problem in fitting experiments is connected to the structure of the data we have to consider (i.e. a huge range of stretches involving mechanical quantities spread over significant differences of magnitude) and the necessity to deal with nonlinear methods. This situation introduces the possibility of non-uniqueness in the optimal set of parameters that may strongly vary in numerical fitting of very similar experimental data. This non-uniqueness can represent a limitation of the theory both in the perspective of a physical interpretation of these parameters and in the numerical applications. In particular, two distinct sets of parameters giving an equally good fitting in tension lead to completely different predictions for other deformations, see [48] for an example.

### 3. A molecular version of the Gent model

A fundamental advance in establishing the connection between continuum mechanics and statistical mechanics can be made based on the Gent model [36]. To have a detailed idea of the features of this model, we refer to the two recent papers [49] and [50]. Here the aim is only to connect this model with the mesoscopic structure of material. In [17], this connection has been provided via the Arruda–Boyce model. Here we show that the Gent model is a *natural* three-dimensional version of a simple cartoon for a single chain entropic model.

We begin by assuming that entropic elasticity represents the right approach for the elasticity of a rubber-like material. In this framework, the first step is to consider a model for the end-to-end distance of a macromolecule. We remember that the energy  $U$  of a single macromolecular chain is given, under the entropic assumption by  $U = -TS$ , where  $T$  is the absolute temperature and  $S$  is the entropy. The entropy is computed as  $S = k_B \ln \Omega$ , where  $k_B$  is the Boltzmann constant and  $\Omega$  is the number of chain conformations realizing a given end-to-end vector  $\mathbf{R}$ . Therefore,  $\Omega$  is proportional to the probability distribution  $p(\mathbf{R})$ . Roughly speaking, as a chain is stretched, we change from a *more* probable state  $A$  to a lesser probable state  $B$  (i.e.  $\Omega(A) > \Omega(B)$ ). In the extreme case of a chain stretched in a straight line  $\Omega = 1$ , so that  $S = 0$  (limit extensibility state).

Several models have been proposed for an ideal chain. In particular, the simple Gaussian assumption is successful in the low stretch regime [1]. On the other hand, if we are interested in the high *stretch* regime (when  $\Omega$  approaches 1), we have to develop more complex and refined models. One such model is the *freely joint chain* (FJC) model, which involves the inverse Langevin function.

**Figure 1.** A cartoon of the ‘FJC tube model’ is obtained from this picture if we consider a straight tube. Then the projection of the rods composing the macromolecule on the axis of the cylinder is easy to obtain. On the other hand, if we consider a curved tube, as is clearly the case in an entangled network, then the same projection depends on the curvature of the axis of the tube. In such a way, we introduce additional parameters (the *persistence* length) and we obtain a different model [51].

Schematically, to understand the FJC idealization of a single molecular chain, we introduce a molecular chain composed by a large number  $N$  of rigid rods, each of the same length  $l$ , hinged together (figure 1). In this FJC scheme, we do not incorporate the observation that the chain is not free in the space, but belongs to a polymeric network introducing several kinds of constraints (e.g., the chains have to avoid each other and therefore the single rods composing the chain are not free to adopt any angle and any possible configurations). Instead, we assume that they are confined to an ideal tube of diameter  $D < l$ .

The projection on the axis of the tube of the single chain is  $\sqrt{l^2 - D^2}$  and because  $L = Nl$ , we find that in a simple one-dimensional setting

$$R^2 = L^2 \left( 1 - \frac{D^2}{l^2} \right). \quad (3.1)$$

On the other hand, it is well known that a rigid rod with a fixed point and free to have any orientation in the space can choose a number of configurations proportional to  $4\pi l^2$ , but if we confine it to a tube, then it is possible to choose only one set out of these orientations, proportional to  $D^2$ . Therefore, the entropy of a single rod can be computed (approximately) as  $k_B \ln(D^2/l^2)$  for a single rigid rod and for the whole chain  $S = Nk_B \ln(D^2/l^2)$ . Thus, using (3.1), we have that the chain entropic energy is

$$G \approx -k_B T \frac{L^2}{l^2} \ln \left( 1 - \frac{R^2}{L^2} \right). \quad (3.2)$$

An interesting feature of this formula is that in the limit (3.2) for  $L \rightarrow \infty$ , we obtain

$$G \approx -k_B \frac{T}{l^2} R^2,$$

i.e. the classical Gaussian approximation. On the other hand, the force associated with (3.2) is

$$f \approx \frac{L^2}{l^2} \frac{k_B T R}{L^2 - R^2}, \quad (3.3)$$

an expression that blows up (as the energy (3.2)) when  $R \rightarrow L$ , i.e. as we approach the full-chain extensibility. This is the characteristic *limiting chain effect*.

We point out that (3.2) is similar to the phenomenological energy density proposed by Gent in [36] for incompressible, isotropic, hyperelastic materials:

$$W = -\frac{E}{6} J_m \ln \left[ 1 - \frac{I_1 - 3}{J_m} \right]. \quad (3.4)$$

Here  $E$  is the small strain tensile modulus for incompressible materials, related to the infinitesimal shear modulus  $\mu$  by the relation  $\mu = E/3$ . The parameter  $J_m$  gives a limit value of  $I_1$  where the

energy grows to infinity and represents a macroscopic counterpart of the chain contour length at the network scale, when the molecular chains reaches the fully stretched state. When  $J_m \rightarrow \infty$  from (3.4), we recover the neo-Hookean model (2.3).

To understand more explicitly the analogy between the previous trivial single chain model and the Gent model, we recall a simple result by Kearsley [52] stating that the first invariant  $I_1$  is equal to three times the square of the stretch ratio of an infinitesimal line element averaged over all possible orientations. This shows that  $J_m$  is a fair (and natural) measure of the average limit (contour) length of the chains composing the polymeric network. This is, moreover, the reason why we observe that when  $J_m \rightarrow \infty$ , (3.4) reduces to the (2.3), i.e. to an isotropic network of Gaussian chains. We may then deduce that the Gent model is a simple and direct generalization of the neo-Hookean strain energy density to take into account the non-Gaussian character of the macromolecular chains with finite contour length.

Another important mathematical aspect in the perspective of numerical applications is the choice of correct approximation of the different proposed constitutive functions. For example, we observe that for a Gent material the generalized shear modulus is a rational function. This is in contrast with the majority of the models considered in phenomenological theories typically based on polynomial constitutive functions, coming from a truncated Taylor expansion. For rational functions it is standard to use *Padé approximants*, not only because they give a better approximation, but also because they take into account the presence of singularities [53], in contrast with polynomial approximations. In the framework of non-Gaussian models, singularities represent a crucial point for a correct material description, as they capture the so-called entropic hardening, and induced deformation and damage localization phenomena observed experimentally. As another important example, we remark that the inverse Langevin function cannot be expressed in terms of elementary functions and that this special function has a singularity when we approach the contour length of the macromolecular chain. Many authors have approximated (for example, in the framework of finite-element computations) this special function by using polynomials, but this is clearly a non-correct approximation because it smooths out the singularity. A rational (but very complex) approximation of the inverse Langevin function is introduced by Treloar in [1] and a Padé approximation was first introduced by Cohen in 1991 [54] (see also [55]). There the approximation proposed is at the sixth order in the stretch. Horgan & Saccomandi [17] realized that when you fix  $J_m$  (the maximum average contour length) and you search for a Padé approximation of the 8-chain model proposed by Arruda & Boyce [43], then you obtain exactly the Gent model at lower order. In such a way, it is possible also to give an *a posteriori* ‘molecular’ interpretation of the Gent model which is exactly equivalent of the one proposed for the Arruda–Boyce model.

Having recalled the interesting physical interpretations of the Gent model, we point out that it belongs to the class of *generalized* neo-Hookean materials and thus it does not reproduce the experimental effects described in §2b in a satisfactory way. A natural question is therefore to understand if we are able to improve it by introducing the  $I_2$  invariant and provide a connection with the mesoscopic structure. To this end it is important to remember that Kearsley showed that the mean square change in area is related to  $I_2$  [52].

Let us go back to the cartoon of the tube in figure 1 to understand how it is possible to introduce the  $I_2$  invariant in the modelling. If the cross-sectional area of the tube changes due to the macroscopic deformation  $f$ , then it is possible to replicate our computations by introducing a multiplicative correction in the logarithmic term in (3.2). A similar idea has been introduced by Kroon [56], where the change of the microscopic tube dimensions has been shown to be proportional to the root mean square change of macroscopic area, i.e. to an averaged term  $\sqrt{I_2}/3$ . Following this idea and using the properties of the natural logarithm, it is easy to deduce that the Gent model has to be modified as follows:

$$W = -C_1 J_m \ln \left[ 1 - \frac{I_1 - 3}{J_m} \right] + C_2 \ln \left( \frac{I_2}{3} \right). \quad (3.5)$$

Here  $C_1$  and  $C_2$  are two constants. Pucci & Saccomandi [57] proposed this model using a purely phenomenological methodology that allows a fitting of the data in uniaxial tension with a relative error kept under the 5% for the whole range of deformation.

Another way to improve the Gent model, but remaining in the generalized neo-Hookean class, is to use a more realistic model for the polymeric chain. In the framework of some biomolecular materials it seems that a better model than the FJC chain of the macromolecular molecules is the worm-like chain (WLC) model. Roughly speaking, we obtain the WLC model by following the previous scheme now with the macromolecule no longer composed by hinged rods, but by hinged *beams*. Alternatively, it is possible to deduce a WLC type energy by considering that the rods are rigid but the tube is curved as in figure 1. As a result, we find that the correlation among adjacent *monomers* is higher than in the FJC model and the singularity is quadratic in the stretch of the molecule. The phenomenological three-dimensional version of the WLC has been considered by various authors (see, e.g. [51]) and we refer the readers to these papers for details.

What we want to propose here is, in the framework of the phenomenological theory of elasticity, a family of strain-energy functions defined as

$$W^{(m)}(I_1) = \frac{\mu}{3} \left[ \frac{1}{2}(I_1 - 3) + \frac{J}{m(1 - (I_1 - 3)/J)^m} - \frac{J}{m} \right], \quad (3.6)$$

where  $m \geq 0$  is the exponent that controls the asymptotic behaviour of the model. Interestingly, for  $J \rightarrow \infty$ , we obtain the classical neo-Hookean model. The generalized shear modulus associated with the family of strain-energy functions (3.6) is

$$Q^{(m)} = \frac{2\mu}{3} \left[ \frac{1}{2} + \frac{1}{(1 - (I_1 - 3)/J)^{m+1}} \right]. \quad (3.7)$$

To study the behaviour of this model, it is convenient to introduce the variable

$$\zeta = \frac{I_1 - 3}{J}$$

such that  $\zeta \in [0, 1[$  and to reduce (3.7) to its dimensionless form, i.e.

$$\frac{Q^{(m)}}{\mu} = \frac{2}{3} \left[ \frac{1}{2} + \frac{1}{(1 - \zeta)^{m+1}} \right]. \quad (3.8)$$

Approaching  $\zeta \rightarrow 1$ , the asymptotic behaviour of (3.8) is

$$\frac{Q^{(m)}}{\mu} \approx -(-1)^m \frac{2}{3(\zeta - 1)^{m+1}}.$$

For  $m = 1$ , we recover the model proposed in [58] to mimic a network of WLC chains. In this case

$$\frac{Q^{(1)}}{\mu} \approx \frac{2}{3(\zeta - 1)^2}.$$

For  $m = 0$ , we obtain a model with the same asymptotic behaviour of the FJC model. Indeed, using some elementary calculus we find

$$W^{(0)} = \frac{\mu}{3} \left[ \frac{1}{2}(I_1 - 3) - J \log \left( 1 - \frac{I_1 - 3}{J} \right) \right] \quad \text{and} \quad Q^{(0)} = \frac{2\mu}{3} \left[ \frac{1}{2} + \frac{1}{(1 - (I_1 - 3)/J)} \right]. \quad (3.9)$$

In this case

$$\frac{Q^{(0)}}{\mu} \approx -\frac{2}{3(\zeta - 1)}.$$

It is interesting to note that the strain-energy function (3.9) is similar, but not identical to the Gent strain energy (3.4).

These simple computations show the strength of the continuum mechanics perspective, which allows the modelling of any kind of asymptotic behaviour when we approach the limiting chain behaviour via simple mathematical considerations. On the other hand, it is clear that the chain confined in a tube gives a special status to the idea of Gent. The synergy between the two points

of view is the key reason of the success of the modelling procedure that we sketched in this section. In the next section, we explore an example of a more systematic and rigorous approach.

## 4. Multi-scale and microstructure-inspired continuum models

The possibility of material design down to the nano-scale has made the request of new multi-scale approaches a strongly appealing field of research (e.g. [18] and references therein).

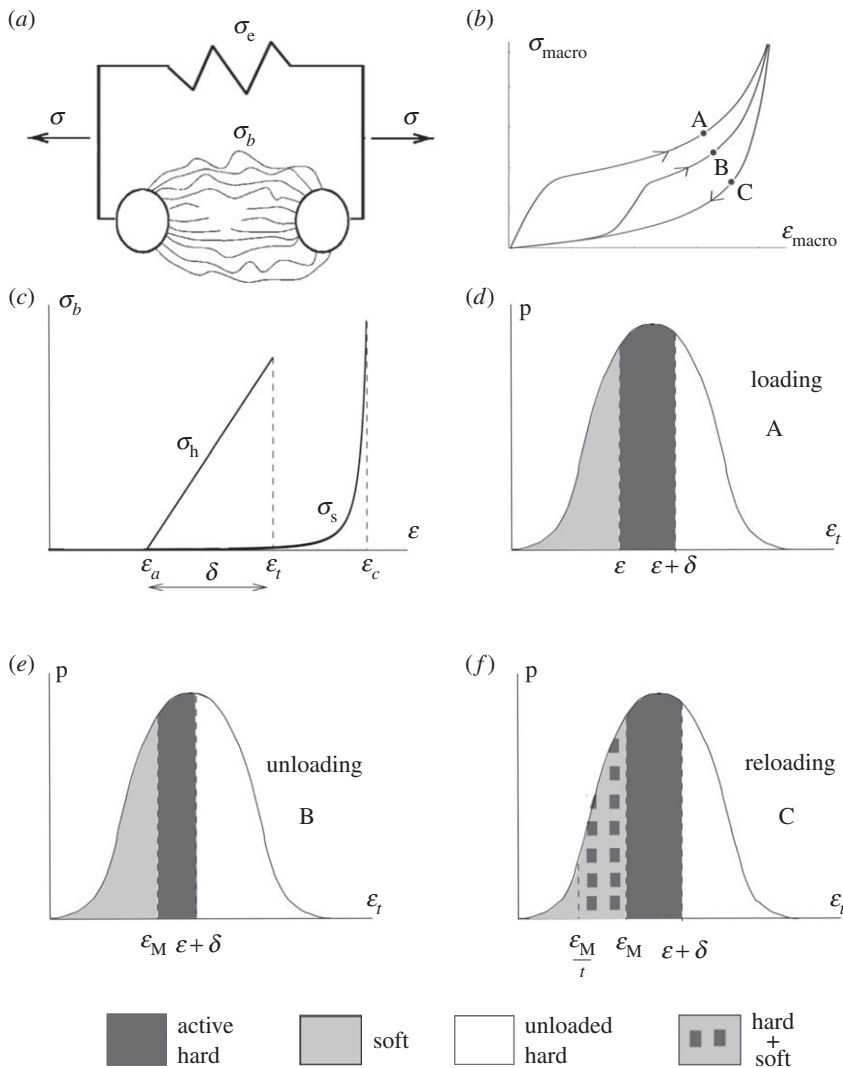

Here we refer to multi-scale theories deducing macroscopic three-dimensional constitutive theories from a model for the single chain mechanical behaviour. A standard approach is to deduce the material behaviour of a real polymeric network by an ‘averaging procedure’ that allows us to go from a single chain to a *bundle* of chains. This idea has been widely used for a long time and several possible methods are used to implement it (see, for example, the discussion in [1] or in [13]). The simplest method is based on the so-called ‘affine assumption’. In this method, we link the macroscopic deformation with the macromolecular network deformation via specific network cells (single chain, 4-chain tetrahedral structure, 8-chain cubic structure, 8-chain octahedral structures, etc.), oriented according to the principal directions of the macroscopic deformation. More general assumptions considering ‘non-affine’ effects or full-network models can be considered.

In reality, an actual description of a macromolecule *network* requires not only the choice of a mathematical average procedure, but also the consideration of many other crucial effects. A network introduces enthalpic contributions due to chain-to-chain (or possibly chain-to-fillers) interactions and the associated complex phenomena of links breakage and re-cross-linking. This discussion is subtle because each link breakage not only induces by definition an enthalpic energy variation, but also, and more importantly, by varying the network conformation, it leads to a variation of the chains contour length and of the network natural configuration. The enthalpic contribution can be considered at the root of many crucial macroscopic effects such as damage, dissipation, anisotropy, residual stretches, deformation and damage localizations, which are all well-known experimental phenomena in rubber and rubber-like materials. The theory is even richer if one considers the possibility of re-cross-linking effects (material healing) that is revealed macroscopically by internal hysteresis cycles. Another important effect is related to single chains models with variable material properties, when the single chain is constituted by several material phases. For example, a soft (entropic) phase corresponding to a poorly entangled macromolecules plus a crystalline phase (typically in forms of  $\beta$ -sheets or  $\alpha$ -helices).

Both the comprehension and the prediction of all these fundamental phenomena and the design of new polymeric and bioinspired materials will benefit, in our opinion, from a real synergic contribution of molecular and macroscopic continuum mechanics phenomenological theories. In this respect both the incredible progress in experiments and material manipulation at the macromolecular scale and the great advances in the extension of nonlinear theory of elasticity to phenomena often considered out of its range of application, are providing the necessary driving force.

To exemplify this possibility, we now describe some recent approaches starting from a microstructure-inspired material constituted by a mixture of an elastic fraction and a breakable fraction. To describe the amorphous character of the network, constituted by chains of different length, we assume that the breakable fraction is constituted by chains that can undergo activation and breaking at different stretches. We then use a Griffith-like method to minimize the total (fracture plus entropic) energy.

In figure 2*a*, we have a cartoon of this idea. The material is composed by a hard and a soft phase (figure 2*c*). The soft phase is modelled using a Gent-like model (i.e. a model taking into account limiting chain extensibility). The hard phase is modelled by just considering a linear behaviour. Roughly speaking, the soft phase represents the entropic energy of the network, whereas the hard phase measures the presence of cross-links and the associated enthalpic contribution. To fix the ideas, imagine that the material is submitted to simple extension. If we increase the strain monotonically, at a certain activation threshold  $\varepsilon = \varepsilon_a$  a polymeric chain of the hard phase is

**Figure 2.** A cartoon of the basic model we propose where the network is composed of entropic non-Gaussian chains and linear elastic springs.

activated (figure 2c) with a stress  $\sigma_h = \sigma_h(\varepsilon)$ . If the strain is increased further there exists another threshold  $\varepsilon = \varepsilon_b := \varepsilon_a + \delta$ , where the cross-link is completely damaged and it stops to have a mechanical function, so that new monomers are available to the chain (soft phase with a new stress  $\sigma_s = \sigma_s(\varepsilon)$ ). To model a real network, we introduce a probability function depending on both  $\varepsilon_a$  and  $\varepsilon_b$  that can be deduced by simple cyclic experiments [16]. This probability describes that the cross-links are not all activated and broken at the same value of  $\varepsilon_a$  and  $\varepsilon_b$ . The presence of an initial elastic matrix of untangled chains is schematized in figure 2a by a parallel spring. The possibility of a full breakage of the link may be simply introduced by assuming  $\sigma_s = 0$ , whereas the possibility of a hard–soft (folded–unfolded, helix–coil, etc.) transition is modelled by considering  $\sigma = \sigma_s \neq 0$  after the link breakage. The possibility of re-cross-linking upon reloading, observed in many rubber-like and biological materials, can be also easily introduced in the model as represented in figure 2f by assuming that the reverse (re-cross-linking) soft  $\rightarrow$  hard transition can be observed upon unloading, as suggested by the experimental behaviour of many polymeric and biological materials. A possible association of the macroscopic hysteric behaviour (points A, B, C in figure 2b) to the microscale network evolution (figure 2d–f) is also represented in the figure.

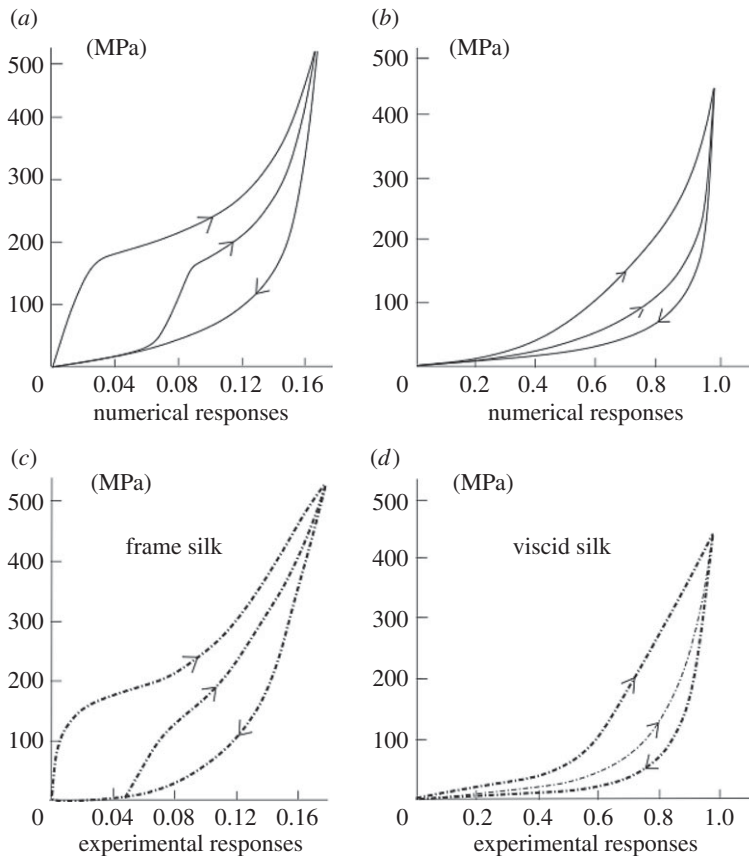

In the various stages of the deformation, the material is composed by a variable amount of active hard and soft phases and the evolution of this mixture can model the strain-hardening phenomena, the stress-softening, the damage and the internal hysteresis of the material. This simple idea allows many degrees of freedom in the modelling of the mechanical behaviour of complex amorphous materials [16,42].

These ideas have been applied to deduce various three-dimensional models with the aim of discussing many mechanical phenomena of relevance for amorphous rubber-like materials. In [59], the Mullins effect in rubber-like solids is described using the notion of limiting chain extensibility associated with the Gent model. In relating this theory to the mechanisms of network alteration and to the pseudo-elasticity theory proposed in [60], it was possible to show the relationship of our basic idea with the Eckart theory of the evolution of the natural configurations as elaborated by Rajagopal & Wineman [61]. In [62], the role of healing was introduced to describe the internal hysteresis of rubber-like materials, and the model was shown to be successful: the experimental behaviour of rubber balloons with internal hysteresis damage has been successfully reproduced in [63]. On the same topic, we point out the approach and the papers by Wineman and co-workers [64–67].

The above idea has been very promising also in the framework of the *mechanobiological* modelling of some biomaterials such as spider silk, see [68], where we modelled the soft phase using a simple Gent type energy of the Worm Like Chain form. Spider silks protein macromolecules have a hierarchical structure with a primary structure composed by an amino acid sequence of highly repetitive glycine and alanine blocks and a secondary structure level composed by short side-chained alanine. Glycine is the main component of the amorphous matrix (the *soft phase*) and on the other hand, nano-fibrils are found in the side-chained crystalline domains in the form of  $\beta$ -sheets (the *hard phase*). A single spider can produce up to seven different types of silk for different uses and each spider and each type of silk has a set of mechanical properties optimized for their biological function. This is possible because the spider is able to control the mixture of the two hard and soft phases. By tuning this mixture it is possible to obtain very different mechanical behaviour as shown in figure 3 [68].

The second approach, applied to protein tissues [69], is a multi-scale method that begins with a detailed description of the energetics at the scale of the single macromolecule (see the cartoon in figure 4a). When we consider the unfolding of giant proteins like titin (crucial for the passive elasticity of muscles), we have to account for a complete description of the force-length macromolecular behaviour that is characterized by a sawtooth stress plateau with each stress jump associated with the unfolding of a  $\beta$ -sheets domain [69] (see the Atomic Force Microscopy experiments of [19] reproduced in figure 4c). The unfolding of the  $\beta$ -sheets ‘dissipates’ energy (as heat) and increases the free monomers available to the chain. In the cartoon of figure 4a, we imagine that the macromolecular chain is composed by rods and many bubbles (here modelled as rigid). Roughly speaking, when we pull the chain we open some bubbles, releasing monomers in the chain. This unfolding process is regulated by an energetic competition between the entropic energy decrease and the enthalpic energy associated with the folded–unfolded transition, modelled here through a classical Ising model. The contour length of the chain increases and the overall result of this structure is shown in figure 4b, where (see [69] for details) we schematize the energy we ‘dissipate’, and figure 4c where we reproduce the experimental saw-tooth force evolution observed by AFM experiments of proteins macromolecules (e.g. [19]). This peculiar plot originates from the discontinuous evolution of the contour length and changes of the entropic energy associated with the successive unfolding events.

The consistent thermodynamic continuum version of these approaches has then been obtained through two different change of scales [70]. First, as the macromolecules are typically characterized by a high number of crystal (hard) domains, we may consider [40] a discrete→continuum limit. We obtain a history-dependent energy, depending on the fraction of unfolding domains, converging for the primary loading path to the convex hull of the energies represented in figure 4b. In this limit, we obtain constant unfolding stress-plateaux approximation of the force-length curve in figure 4c. Then, based on the choice of an appropriate

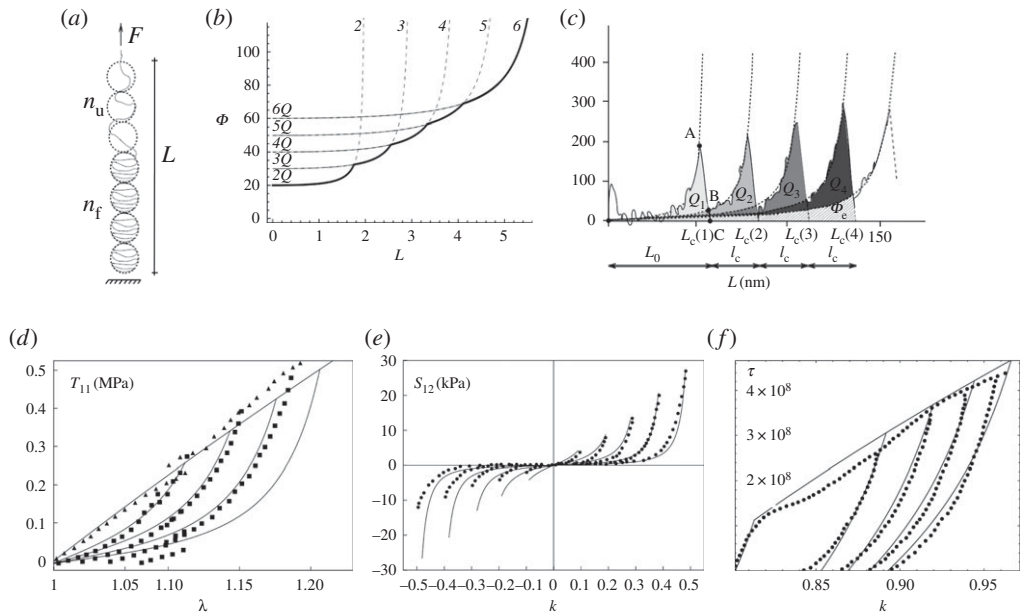

**Figure 3.** In the curves in (a,c), we have an ideal material composed by a mixture where the hard phase has a principal role. In (b,d), we have an ideal material where the soft phase plays the main role.

cell structure [13], we deduce the macroscopic energy, with the elastic moduli directly related to the network scale properties of the material (contour length, Kuhn length, persistent length, number of chains, unfolding energy of the  $\beta$ -sheets). When this limit is done carefully it is possible to introduce several effects, such as residual stress or growth effects, crucial for a realistic description of biological tissues. More specifically, in our model [70], we connected the macroscopic stretches to the chains elongations (the Cauchy–Born rule) based on the affine hypothesis [74] and an 8-chain network cell [13]. The predictability of the resulting model is described in figure 4d,e for the cyclic loading of mouse skin reproduced by Muñoz *et al.* [71] and the shear behaviour of pig (passive) myocardium tissues reproduced by Dokos *et al.* [72], respectively.

The numerical extension of the model to the 3-chain approach has been exemplified in figure 4f, where we reproduce the experimental behaviour of Senegalensis Nephila spider silks from Vehof *et al.* [73]. The introduction of the 3-chain scheme lets us model the important anisotropic effect induced by the directional-dependent unfolding, due to the chain alignment along the most stretched directions.

Summarizing, by using a two-state scheme and a Griffith-like total energy minimization method, i.e. the minimization of the total (entropic plus unfolding) energy [69], we have been able to describe the unfolding of multi-domain macromolecules (proteins, silks, polysaccharides, nano-polymers) in a fully analytical framework. In doing so, we have been able to master the role of the different energetic components regulating the unfolding evolution. The explicit analytic deduction of the history-dependent, strongly nonlinear behaviour of the material has been

**Figure 4.** The sub-plot (a) shows a cartoon of the macromolecule composed by rods and bubbles, i.e. structures that contain a reservoir of monomers and if opened change the contour length of the molecule. In (b), we plot the total energy (Griffith-like) minimization method. Opening of a bubble has a twofold effect: it dissipates a certain amount of energy  $Q$  and it increases the contour length thus changing the elastic curve. Despite this complexity, the minimization of the overall energy is possible. The corresponding sawtooth force [69] end-to-end length diagram is represented in (c), reproducing the AFM experimental behaviour of the single macromolecule in [19]. In (d) and (e), based on an 8-chain cell scheme, we reproduce [70] the cyclic loading for mouse skin studied in [71] and the shear cycles of pig (passive) myocardium tissues reported in [72], respectively. In (f), based on a 3-chain scheme, we reproduce the experimental behaviour of *Senegalensis Nephila* spider silks from [73].

presented in [70] where the damage, softening, growth, residual stretches have been analytically deduced, starting from the microscopic properties of the material. Roughly speaking, we obtain a Gent-type constitutive law with a history-dependent limit threshold  $J_o$  and a variable natural configuration, based on the classical multiplicative decomposition of the deformation gradient in a growth and in an elastic component. The approach synthesized above shows the potentiality of deducing an actual continuum mechanics method, based on multi-scale analyses, that can be used to explain many complex phenomena where the material alteration at the network scale of amorphous macromolecular materials is the driving force of some type of *phase transition* [75].

## 5. Concluding remarks

We provided a synthetic (and incomplete) overview of how it is possible to introduce low-scale effects in macroscopic modelling of polymeric modelling using both microstructure inspired or multi-scale approaches. Our survey does not claim in any way to be a detailed review of the literature. Rather, it is an introduction to the modelling philosophy contained in [42,70]. In [42], we were able to prove that if at the mesoscale the polymeric network is constituted by distributions of elastic and breakable links with variable activation and fracture thresholds and we use a Griffith method, then we are able to describe the main experimental effects observed at the microstructure and macroscopic scale in disordered materials undergoing damage. Moreover, via this model we are able to generate non-convex macroscopic energies from micro-mechanics considerations. The thermodynamical consistency of the model, the three-dimensional extensions, and the possibility of deducing the corresponding macroscopic moduli, have been phenomenologically introduced in [16], based on a classical ‘plasticity theory type’ activation and breaking criterion, and explicitly

deduced through a fully multi-scale philosophy in [70]. Several successful applications of this idea have already been provided, but many other interesting applications are feasible.
