The diversity of characteristics for the host of recently discovered exoplanets opens up a great deal of fertile new territory for geophysical fluid dynamics, particularly when the fluid flow is coupled to novel thermodynamics, radiative transfer or chemistry. In this paper, we survey one of these new areas—the climate dynamics of atmospheres with a non-dilute condensible component, defined as the situation in which a condensible component of the atmosphere makes up a substantial fraction of the atmospheric mass within some layer. Non-dilute dynamics can occur for a wide range of condensibles, generically applying near both the inner and the outer edges of the conventional habitable zone and in connection with runaway greenhouse phenomena. It also applies in a wide variety of other planetary circumstances. We first present a number of analytical results developing some key features of non-dilute atmospheres, and then show how some of these features are manifest in simulations with a general circulation model adapted to handle non-dilute atmospheres. We find that non-dilute atmospheres have weak horizontal temperature gradients even for rapidly rotating planets, and that their circulations are largely barotropic. The relative humidity of the condensible component tends towards 100\% as the atmosphere becomes more non-dilute, which has important implications for runaway greenhouse thresholds. Non-dilute atmospheres exhibit a number of interesting organized convection features, for which there is not yet any adequate theoretical understanding.
1. Introduction

One of the most remarkable scientific developments of the past two decades is the emergence of a capability to detect and characterize planets outside our own Solar System. This has led to a growing catalogue of exoplanets, currently in the thousands [1]. This catalogue is abundant in planets of a type that have no real counterpart in our own Solar System [2], and pose challenges to existing theories of planetary formation and evolution. Many of the planets are known to have atmospheres or expected to have atmospheres, and in some cases (though primarily so far only for hot gas giants) there has even been progress in characterizing atmospheric composition and some aspects of atmospheric thermal structure. Understanding the climate dynamics of these novel atmospheres is an essential part of formulating observational strategies and interpreting observations. Climate dynamics also enters into determining the long-term evolution of atmospheres and of the surface conditions; the question of habitability occupies a central position in such studies, but even thoroughly uninhabitable planets can yield important insights. Exoplanets have opened a pathway to a new adventure in geophysical fluid dynamics, especially when the fluid dynamic is linked to novel forms of radiative transfer, thermodynamics and atmospheric chemistry. This presents a unique opportunity to imagine atmospheres before they have been observed, with the virtual assurance that, given the billions of exoplanets in our galaxy alone, almost anything we can imagine is likely to be out there somewhere.

The new era of exoplanet exploration has stimulated work on such novel climate phenomena as climates of planets in tide-locked or other low-order spin–orbit configurations where the length of day is comparable to the length of year [3,4], climate of transonic rock vapour atmospheres on planets with permanent day-side magma oceans [5], climate of hot Jupiters and hot mini-Neptunes [6,7], and climate of planets subject to the infrared-rich illumination by red dwarf stars [8]. This list is far from exhaustive, and grows by leaps and bounds on a practically monthly basis. In this paper, we will focus on some frontiers in geophysical fluid dynamics associated with atmospheres in which the condensible component is non-dilute.

Water vapour is the chief condensible component of the Earth’s atmosphere, and it is dilute in the sense that its molar concentration is never more than a few per cent, being largest in the warm tropical lower atmosphere. Many aspects of conventional terrestrial climate models make heavy use of approximations appropriate to the dilute limit. For example, while the latent heat released by condensation is a central driver of the general circulation, the pressure changes due to mass loss from rainfall have at best minor dynamical consequences. Similarly, on the present Earth water vapour has only a minor (though not entirely negligible) effect on buoyancy. There are, however, many planetary circumstances under which water vapour or other condensibles can become non-dilute, as detailed in §3a(i). Even in the Solar system, non-dilute dynamics is involved in consideration of the runaway water vapour greenhouse on Venus, the methane ‘hydrological’ cycle on Titan, and the effects of CO2 condensation on both present and ancient Mars. The hydrological cycle on the Earth would edge into non-dilute behaviour if the planet were as little as 20°C warmer. Non-dilute atmospheres occur at both the inner edge of the conventional habitable zone where water vapour is the condensible, and at the outer edge where CO2 is the condensible. They also can be expected in a wide variety of other planetary circumstances, as detailed in §3a(i).

For non-dilute atmospheres, the mass lost via precipitation leads to significant horizontal pressure gradients, and thus opens the door to a range of novel dynamical phenomena. Transport of energy and angular momentum by precipitation potentially become major effects in non-dilute atmospheres. Convection in non-dilute atmospheres can be quite different from the familiar dilute case, and poses a challenge to current approaches to convection parametrization, not least because of the challenge of properly enforcing enthalpy conservation in the course of adjustment. There are boundless possibilities for surprises in the collective behaviour when all these things are linked together and coupled to the rest of the climate system.

In many of the examples to be discussed in this paper, the condensible component will be taken to be water vapour. However, the principles illustrated are general and apply equally to
any condensible component, save that the typical temperature at which the atmosphere becomes non-dilute will depend on the thermodynamic properties of the condensible component and both the inventory and thermodynamic properties of the non-condensible background gas. Similarly, we will use terms like ‘dry’, ‘moisture’ and ‘relative humidity’, which commonly apply to water, to refer to analogous concepts for other condensibles.

Any problem involving condensation must confront the difficult issue of microphysics—loosely speaking the kinetics governing initial formation of condensate, the subsequent growth of particles by deposition and coagulation, their transport by precipitation, and their mass loss due to evaporation as they fall through subsaturated layers of the atmosphere. These phenomena are all of considerable importance. For example, a parcel of atmosphere which is cooled by lifting or by radiative cooling can become highly supersaturated before condensate forms, in the absence of suitable cloud condensation nuclei (CCNs) to serve as sites to trigger initial formation of condensate. The density of CCNs can control the initial size of condensate particles, which in turn governs how long they take to grow to a size sufficient to cause appreciable sedimentation. The physical chemistry determining when a particle is a good CCN, and the factors governing the sources and sinks of CCNs pose formidable challenges even for the well-observed case of dilute condensation of water vapour on the Earth. There is little doubt that microphysics will prove to be of great importance in governing condensible dynamics in the non-dilute and chemically diverse atmospheres of exoplanets, but we will not attempt to address such issues in this work.

As an initial step in the exploration of non-dilute dynamics, we will work in a highly idealized world in which there is sufficient supply of CCN that condensation always keeps the system from becoming supersaturated, in which condensate particles grow sufficiently quickly that they can be regarded as instantaneously removed by precipitation, and in which no mass of precipitate is lost on the way to the planet’s surface condensate reservoir.

We begin in §2 with a general discussion of the circumstances in which dynamical effects result in weak horizontal temperature gradients in the absence of condensation effects. Analytical results on the nature of non-dilute climates are developed in §3. The exo-FMS general circulation model, designed to remain valid for non-dilute circulations, is described in §4, and in §5 we present some preliminary simulation results showing the transition from dilute to non-dilute behaviour on rapidly rotating planets. Our principal findings, and directions for future research, are summarized in §6.

2. Preliminaries: the weak temperature gradient limit

One of the key properties of non-dilute atmospheres which we demonstrate is that they are characterized by weak horizontal temperature gradients. Therefore, it is useful to examine other dynamical regimes which produce weak temperature gradients (WTGs) without relying on non-dilute physics. Loosely speaking, at latitudes where the effective Coriolis force is weak, temperature gradients are also weak because the pressure gradients associated with strong temperature gradients cannot be balanced by the Coriolis forces produced by winds of a magnitude compatible with other dynamical constraints (e.g. angular momentum conservation). The Coriolis parameter giving the local effect of rotation is \( f = 2\Omega \sin \phi \), where \( \Omega \) is the angular rotation rate of the planet and \( \phi \) is the latitude. Thus, the weak gradient behaviour always applies near the equator, and indeed this forms the basis of the standard conceptual model of the Earth’s tropical circulation (see [9] for a summary of the ideas and their history). For a slowly rotating planet, the WTG approximation holds globally. This regime is of particular importance for tide-locked planets about low-mass stars, since tide-locking can occur in long-period orbits in that case, and in particular within the conventional habitable zone of M-dwarf stars. The application of WTG in this regime was elaborated in [4]. But what determines the value of \( \Omega \) for which the rotation rate can be considered slow enough for the WTG approximation to be valid? A little dimensional analysis helps to resolve this question.

The basic principles are sufficiently illustrated by examining the zonal momentum equation written in local Cartesian coordinates near a given latitude. If we assume the hydrostatic
approximation, the steady-state zonal momentum equation takes the form

\[ u \partial_x u + v \partial_y u = -fv - \partial_x g Z', \]  

(2.1)

where \( Z'(x,y,p) \) is the height of the isobaric surface at pressure \( p \) with the mean value over the surface removed and the derivatives are taken at constant pressure. Now let us non-dimensionalize velocities by the characteristic scale \( U \), lengths by scale \( \ell \) and \( Z' \) by a depth scale \( D \). Then, in non-dimensional form the equation becomes

\[ \text{Ro}^2(u \partial_x u + v \partial_y u) = -\text{Ro} v - A^2 \partial_x Z', \]  

(2.2)

where

\[ \text{Ro} \equiv \frac{U}{f\ell}, A \equiv \sqrt{\frac{gD}{f\ell}} \]  

(2.3)

and all variables have been replaced by their non-dimensionalized counterparts. The parameter \( A \) is the ratio of the radius of deformation \( L_d \equiv f^{-1}\sqrt{gD} \) to the length scale \( \ell \).

From the hydrostatic relation, it can be concluded that the non-dimensional \( Z' \) characterizes the magnitude of temperature fluctuations on an isobaric surface. Specifically,

\[ \frac{\partial Z'}{\partial \ln p} = -\frac{H(\bar{T}(p))}{D} \frac{T'}{\bar{T}(p)}, \]  

(2.4)

where \( \bar{T} \) is the horizontal mean over the isobaric surface, \( H \) is the corresponding local scale height and \( T' \) is the deviation from \( \bar{T} \). Since \( \ln p \approx -z/H \), it follows that \( Z' \) is small if and only if the temperature variations (relative to the mean) on an isobaric surface are small.

The familiar quasi-geostrophic limit for rapid rotators applies for \( \text{Ro} \ll 1 \) with \( A^2 = O(\text{Ro}) \), in which case the dominant balance is between the Coriolis force and the pressure gradient force. This situation permits large geostrophically balanced horizontal temperature gradients.

Given that \( L_d \) represents the radius of influence of steady-state response to localized heating with vertical scale \( D \), the usual naive criterion for WTGs over length-scale \( \ell \) is \( L_d \gg \ell \), i.e. \( \Lambda \gg 1 \). This would correspond to globally valid WTG behaviour if \( \ell \) is taken to be the planet’s radius. However, for slow rotators we typically have \( \text{Ro} \gg O(1) \), which is indeed the dynamical definition of a slow rotator. From equation (2.2), it is evident that \( \Lambda \gg 1 \) is not sufficient to guarantee WTG behaviour; one in fact also needs \( \text{Ro}/\Lambda \ll 1 \). The typical situation in which WTG behaviour is expected involves large \( \Lambda \) with \( \text{Ro} \) order unity or larger, but \( \text{Ro} \) must not be too large; otherwise, strong pressure gradients can be balanced by strong wind gradients. Even if \( \Lambda \gg 1 \), WTG behaviour can be broken by the generation of very strong super-rotating winds, for example. The appearance of \( \text{Ro} \) in the criterion for WTG validity makes our scaling theory diagnostic rather than fully predictive, since \( \text{Ro} \) is not an externally imposed parameter but rather a property that in principle should be deduced from the planetary conditions driving the circulation in a complete scaling theory. Consistency can be checked by computing a circulation based on the WTG approximation, and then evaluating whether the constraint on \( \text{Ro} \) is satisfied. The way this check plays out will depend on such things as the strength of the differential stellar heating of the planet’s atmosphere and the radiative damping time, among many other factors. Because of the lack of a general theory determining the strength of super-rotating winds, carrying out such a programme poses a considerable challenge, and we shall not attempt to meet it here. One would also need to consider the possibility that atmospheres might support a WTG state with weak winds, but also an alternative state with strong winds and temperature gradients. Some attempts at formulating criteria for WTG validity based entirely on externally imposed parameters are presented in [10,11].

Note that \( \text{Ro}/\Lambda = U/\sqrt{gD} \), which is a Froude number, and that for deep motions where we can take \( D = H \), then the denominator becomes \( \sqrt{RT} \), which is the speed of sound up to an order unity factor. In this case, \( \text{Ro}/\Lambda \) is in fact a Mach number, whence we can conclude that \( \Lambda \gg 1 \) is sufficient to assure WTG behaviour so long as the planetary winds are strongly subsonic. In the Cartesian-coordinate momentum equation given in equation (2.1), violation of the strongly subsonic
condition implies that the nonlinear momentum advection becomes available to balance pressure gradients; on a sphere, another important nonlinear term is available—the cyclostrophic terms \((1/a)uv \tan \phi\) in the zonal momentum equation and \((1/a)u^2 \tan \phi\) in the meridional momentum equation, where \(a\) is the radius of the planet. This term has the same scaling as the momentum advection term for planetary scale circulations, where \(a\) is the appropriate length scale. Although inclusion of the term does not change the conditions for WTG to be valid, it does introduce cyclostrophic balance of the pressure gradients due to strong temperature gradients as a possible state when the conditions for validity of WTG are violated.

To assess the occurrence of WTGs in deep layers on the planetary scale, we set \(\ell\) to the planetary radius \(a\) and \(D\) to the scale height \(H = RT/g\), where \(T\) is a typical temperature of the atmosphere and \(R\) is the gas constant corresponding to the dominant atmospheric composition. In that case \(\Lambda = \sqrt{RT/\Omega a}\) and the criterion becomes independant of the surface gravity. For Earth \(\Lambda = 0.62\), and WTG behaviour is confined to the tropics. GJ1214b with an H\(_2\)O atmosphere at 700 K would have \(\Lambda = 0.7\), and would thus be in an Earth-like regime that could support strong extratropical temperature gradients. With an H\(_2\)-dominated atmosphere, GJ1214b would have \(\Lambda = 2.1\), owing to the greater scale height of the hydrogen atmosphere, and would exhibit WTG behaviour more globally. In the Solar system, Titan has \(\Lambda = 15\) and is deep in the WTG regime. A tide-locked GJ581c with a CO\(_2\) atmosphere at 700 K would have \(\Lambda = 6\) while the more weakly illuminated GJ581d with the same kind of atmosphere at 250 K would have \(\Lambda = 17\) and be in a Titan-like regime.

The case of Venus illustrates the difficulty of developing a fully predictive scaling theory for WTG validity. For Venus, \(\Lambda \approx 100\) near the surface and \(\Lambda \approx 50\) at the colder temperatures of the high altitude cloud deck but in either case one would expect Venus to be deeply into the WTG regime. Indeed, there is little horizontal temperature gradient near the surface of Venus. However, at the level of the cloud deck the temperature difference between pole and equator is of the order of 30 K [12], which is similar to the meridional temperature variation on the Earth. The relatively large temperature gradient in the Venus cloud deck is made possible by cyclostrophic balance associated with the strong super-rotating winds in the upper atmosphere of Venus. Based on typical wind speeds of 100 m s\(^{-1}\) [12], \(Ro/\Lambda \approx 0.5\), which confirms the importance of the nonlinear cyclostrophic terms in the momentum equation. Without an estimate of the Venusian wind speeds—from observations, accurate simulations or theory—it would not, however, be possible to anticipate that WTG should break down in the upper atmosphere of Venus.

Even for slow rotators with weak winds, a large horizontal temperature gradient can be supported if it exists only in a vertically thin layer, as shallow temperature anomalies create little pressure gradient. This remark applies anywhere in the atmosphere, but shallow temperature anomalies typically form near the surface of a planet with a distinct surface, in cases where thermal coupling between the surface and the overlying atmosphere is sufficiently weak. For example, in the tide-locked simulations reported in [4], surface temperature variations reported in [4], surface temperature variations are sufficient to allow a pool of open water having temperatures above 300 K near the substellar point even though the rest of the planet is frozen over and has nightside temperatures as low as 200 K. These strong surface temperature variations coexist with free tropospheric temperatures that are very nearly uniform in the horizontal.

### 3. Analytical results on non-dilute atmospheres

#### (a) Thermodynamic fundamentals

#### (i) When is non-dilute dynamics important?

When a planet has a condensible reservoir at the surface, the partial pressure of the condensible at the surface will be determined by the Clausius–Clapeyron relation, yielding \(p_c(p_s) = p_{c,\text{sat}}(T_s)\), where \(p_s\) is the surface pressure, \(T_s\) is the surface temperature, \(p_c\) is the condensible partial pressure and \(p_{c,\text{sat}}\) is the saturation vapour pressure of the condensible. The exponential increase
in saturation vapour pressure with temperature will always lead to non-dilute behaviour at sufficiently high temperatures. The threshold temperature increases with the amount of non-condensible gas in the atmosphere, and also depends on the thermodynamic parameters of the condensible and non-condensible gases. Suppose that the mass path (mass per square metre of planetary surface) of the non-condensible is $\mu_\text{nd}$, and define the pressure $p_{\text{nd}} \equiv \mu_\text{nd} g$, where $g$ is the surface gravity. This pressure is the surface pressure when there is essentially no condensible in the atmosphere, and it is approximately the partial pressure of non-condensible gas at the surface when the atmosphere is dilute. Atmospheres over a surface reservoir generally become non-dilute first at the surface, where the vapour pressure is greatest; for atmospheres in which temperature decreases with height, as in convective tropospheres, the behaviour becomes more dilute as altitude increases, owing to the corresponding decrease in saturation vapour pressure. Because of the flatness of the moist adiabatic temperature profile in the strongly non-dilute limit (§3a(ii)), strongly non-dilute atmospheres can develop deep non-dilute layers.

The actual non-condensible partial pressure at the surface deviates from $p_{\text{nd}}$ as the atmosphere becomes non-dilute, but comparing the surface vapour pressure to $p_{\text{nd}}$ still serves as a useful measure of the threshold of the non-dilute regime. Here, we adopt the criterion that non-dilute effects begin to become significant at a temperature such that the saturation vapour pressure at the surface equals 10% of $p_{\text{nd}}$, corresponding approximately to a 10% molar concentration of the condensible; the atmosphere becomes strongly non-dilute at somewhat higher temperatures. The threshold temperature depends on $p_{\text{nd}}$ and the thermodynamic parameters of the condensible. When $p_{\text{nd}} = 0$, the atmosphere is strongly non-dilute regardless of the temperature, though at low enough temperatures the atmosphere may be exceedingly thin and may in fact be too thin to act as a continuum fluid. The threshold temperature increases monotonically with $p_{\text{nd}}$.

In table 1, we show the threshold temperature for selected substances making up the surface condensate reservoir, at $p_{\text{nd}} = 0.1$ bar and $p_{\text{nd}} = 1$ bar. Even in the presence of a significant non-condensible background, non-dilute behaviour can occur across a wide range of temperatures and background atmospheric pressures, including cryogenic atmospheres with condensing N$_2$, rock vapour atmospheres such as might occur on rocky planets like Kepler10b and 55 Cancri Ae in close orbits about their stars, and all points in between. The rock vapour case is represented by carbon, iron, enstatite and (on the low end for substances considered 'rocks or minerals' on the Earth) sulfur, but there are many other possibilities in a similar range, including sodium and SiO. The threshold temperature for non-dilute behaviour, if based on molar concentration, depends on

Table 1. Threshold temperature $T_{\text{nd}}$ above which behaviour begins to become non-dilute at the surface. $p_{\text{nd}}$ is the surface pressure the non-condensable gas would have in the absence of any condensible, and is a measure of the mass of non-condensable in the atmosphere. The system is considered to be on the threshold of non-dilute behaviour when the molar concentration of condensible at the surface equals 10%, $p_{\text{nd}}$ is given in bars, and $T_{\text{nd}}$ in kelvins. Data for Fe and MgSiO$_3$ are from [13–15].
but not on the composition of the non-condensible gas, so long as the background gas remains non-condensing over the range of temperatures under consideration. For example, around 60 K one can have condensing N\textsubscript{2} in a background of non-condensing H\textsubscript{2} and He, or at temperatures around 180 K condensing CO\textsubscript{2} in a background of non-condensing H\textsubscript{2}, He and N\textsubscript{2}. The relative molecular weights of the condensible and non-condensible do, however, affect the mass fraction of the non-condensible at a given molar concentration, and many physical effects (e.g. surface pressure changes due to precipitation) are more directly tied to mass fraction than molar fraction. Viewed in terms of mass fraction, condensing CO\textsubscript{2} in non-condensing H\textsubscript{2} would be much more non-dilute at the CO\textsubscript{2} threshold temperatures given in table 1 than would condensing H\textsubscript{2}O in non-condensing CO\textsubscript{2} at the H\textsubscript{2}O threshold temperatures.

A planet with a condensate reservoir at the surface will exhibit non-dilute dynamics when the surface temperature exceeds the threshold corresponding to the composition of the condensible and the amount of non-condensible background gas in the atmosphere. For this situation to apply, there must be enough total inventory of condensible substance that there is some left in the surface condensed reservoir at temperatures high enough to make the atmosphere non-dilute. The non-dilute layer in this case will extend upwards from the surface.

This situation occurs over a liquid water ocean (given sufficient total water inventory) as the inner edge of the habitable zone—defined by the water vapour runaway greenhouse—is approached from the habitable side. It also occurs over a liquid CO\textsubscript{2} ocean or a CO\textsubscript{2} glacier somewhat past the outer edge of the conventional habitable zone, near the point where a CO\textsubscript{2} runaway occurs. This would typically occur on planets illuminated somewhat more faintly than current Mars, but which (unlike current Mars) are sufficiently carbonate-rich and which have sufficiently active tectonics to support substantial outgassing of CO\textsubscript{2} from the interior. Non-dilute dynamics also generally prevails during the window of time when a planet is actually undergoing a runaway, but before it has lost its surface condensate reservoir to the atmosphere. There is only a narrow window of time of some thousands of years during which this situation persists, but it is still important to understand the dynamics in this regime, since clouds or subsaturation could in principle act to arrest the runaway.

Given a sufficient inventory of condensible, non-dilute dynamics will generically occur on any planet whose instellation is below the threshold for runaway with regard to its condensible substance, but whose atmosphere also contains enough of a powerful non-condensing greenhouse gas to bring the surface temperature to the threshold where non-dilute behaviour sets in. This occurs because a planet cannot enter a runaway state if the instellation is below a certain threshold (called by some the K-I limit [8]), no matter how high the surface temperature is made. The non-condensing greenhouse gas must be a potent one, otherwise the increase in temperature it causes as more is added to the atmosphere can be outstripped by the increase in the threshold temperature for non-diluteness, associated with the increase in $p_{a0}$. The collisional opacity of non-condensing N\textsubscript{2} on Titan brings methane to the brink of non-dilute behaviour [16]. The Earth’s atmosphere would start to become non-dilute if the CO\textsubscript{2} content increased to the point that surface temperatures exceeded 320 K, a situation that could have occurred during a post-Snowball hothouse [17], or on a watery world with insufficiently strong silicate weathering. On planets with an H\textsubscript{2}-supported greenhouse [18], non-dilute dynamics could occur with regard to many of the condensibles listed in table 1. For example, consider a planet with a CO\textsubscript{2} glacier at the surface, in an orbit such that the absorbed stellar radiation is 17 W m$^{-2}$ averaged over the surface. If the only source of atmosphere were sublimation of CO\textsubscript{2} from the glacier, the surface temperature would be about 132 K and the planet would have a thin non-dilute pure CO\textsubscript{2} atmosphere with surface pressure of 45 Pa. Using the same radiative transfer calculation as described in [18], giving the planet a 1 bar H\textsubscript{2} background atmosphere would raise the surface temperature to 200 K and the surface CO\textsubscript{2} partial pressure to 1.6 bar, resulting in a thick strongly non-dilute atmosphere. (This calculation assumes a surface gravity of 17 m s$^{-2}$, which is typical for a rocky super-Earth.) If the initial atmosphere, instead of being pure CO\textsubscript{2} had also contained 0.1 bar (10$^4$ Pa) of non-condensing N\textsubscript{2} (which is not enough to add significant opacity), then the addition of the H\textsubscript{2} would have transformed the dynamics from strongly dilute
to strongly non-dilute. Similar H$_2$ supported non-dilute regimes can easily be found for NH$_3$, CH$_4$ and N$_2$. Where N$_2$ is present, either as a condensible or as a non-condensible background gas, the N$_2$–H$_2$ collisional continuum can provide an additional source of opacity [19].

The cold low-pressure atmospheres that form by sublimation from icy bodies form another important class of atmospheres, where non-dilute dynamics is important. This regime is familiar from the case of Triton in the Solar system, which has an approximately 2 Pa global N$_2$ atmosphere, which is already thick enough to exhibit interesting dynamics as a continuum fluid [20]. Similar atmospheres would occur for planets enveloped in a global CO$_2$ ice glacier, though we have no examples of such a planet in the Solar system; while there are no exoplanet observations that confirm the existence of such a planet, this sort of behaviour is expected on any planet in a sufficiently distant orbit whose tectonics and composition support substantial outgassing of CO$_2$. Water ice can also feed a significant pure water vapour atmosphere. In the Solar System, Europa is too cold to do this, as the vapour pressure of water at the subsolar point is of the order of $10^{-12}$ Pa. However, for a Snowball Earth with a surface temperature of 265 K and no other atmosphere besides that sublimated from the water ice surface, the surface pressure would be 305 Pa, or half that of the present Mars. Such thin, pure water vapour atmospheres have been studied in connection with the loss of water to space and the formation of abiotic oxygen signatures [21]. In any of these cases, non-dilute behaviour can survive the addition of a background non-condensible gas (e.g. H$_2$ in the condensing N$_2$ case, or N$_2$ in the condensing CO$_2$ or H$_2$O cases) if the surface temperature is increased sufficiently owing to some combination of higher instellation or addition of a non-condensible greenhouse gas.

Another class of low-pressure pure-condensible atmosphere forms when the rate of heat loss from the condensible gas is so great that the gas does not travel very far from its source before most of it condenses back out onto the planetary surface. In such cases, the strong pressure gradients typically drive supersonic flow. Such atmospheres were first studied by Ingersoll et al. [22] in connection with local SO$_2$ atmospheres on Io, which can be sourced either from sublimation of SO$_2$ frost at the subsolar point or from transient volcanic outgassing. Ironically, similar behaviour has been proposed for extremely hot rock vapour atmospheres, such as probably occur on Kepler 10b [5]. Many volatiles are possible in rock-vapour atmospheres, but for 55 Cancri Ae we highlight carbon as an intriguing possibility because of conjectures that this planet might be a carbon-rich body with a graphite surface [23]. The dynamics of local supersonic or transonic atmospheres are very different from the hydrostatic circulations treated in general circulation models based on the primitive equations. This contrasts with the thin N$_2$ atmosphere of Triton, which is global and largely subsonic. A general theory determining when one gets local versus global atmospheres has not yet been formulated. Additionally, the introduction of a sufficient inventory of non-condensible background gas would presumably even out surface pressure variations and result in a subsonic hydrostatic circulation regime, but the way the circulation makes the transition from supersonic and local to subsonic and global as the non-condensible inventory increases has not yet been systematically explored.

Non-dilute behaviour can occur aloft without a surface reservoir of condensible; this would be the typical situation in a post-runaway atmosphere in which the surface ocean or glacier has been depleted so that the lower atmosphere becomes hot and unsaturated. Non-dilute condensing dynamics aloft does not even require the presence of a distinct planetary surface at all. This is important because of the prevalence of fluid super-Earths such as GJ1214b. One of the conjectured compositions for GJ1214b is nearly pure water vapour, and while GJ1214b itself is too hot for water vapour to condense to any appreciable degree within the atmosphere, a similar planet in a somewhat more distant orbit would inevitably have a non-dilute condensing layer. Under some circumstances, to be outlined below, the layer could remain non-dilute even in the face of admixture of some non-condensible background gas such as H$_2$ or N$_2$.

The lifted condensation level is determined by the relation

$$p_{c\text{sat}}(T_{\text{dry}}(p_{lcl})) = n p_r,$$  

(3.1)
Figure 1. Configuration of an atmosphere with a deep non-condensing layer and a condensing layer aloft. This is typical of the situation in which the condensate reservoir at the surface (if there is one) has been depleted, or on gaseous planets with no effective surface at all. $p_{\text{cl}}$ is the lifted condensation level, and $\eta = p_c/p$ is the molar concentration of the condensible substance.

where $T_{\text{dry}}(p)$ is the dry adiabat corresponding to the composition of the atmosphere and $\eta$ is the (constant) molar concentration of the condensible in the non-condensing layer, which is assumed to be well mixed. This relation proceeds directly from the definition of $\eta$. It follows that the condensing layer will be non-dilute when $\eta$ exceeds a specified threshold value (10% in the criterion we have been using).

The condensing layer in figure 1 can be eliminated if the temperature of the upper atmosphere—presumed to be in radiative equilibrium—is sufficiently hot that the atmosphere never intersects the condensation threshold. This would typically happen as a result of strong absorption of shortwave stellar radiation, but even if the upper atmosphere is in pure infrared radiative equilibrium, the radiative equilibrium temperature of the upper atmosphere can be approximately uniform in height in the optically thin portion of atmospheres with broadband absorbers [8, ch. 4], and it is possible for this temperature to be above the condensation threshold.

Figure 1 assumes a convective layer below the condensing layer, but the situation does not change greatly if the deep atmosphere is radiative instead, since pure infrared radiative equilibrium for an optically thick atmosphere (even one that is only optically thick in a small portion of the spectrum) also has temperature decreasing with altitude. On the other hand, if the atmospheric absorption of shortwave stellar radiation is so strong that essentially all of the instellation is depleted in the upper atmosphere, and if in addition the atmosphere does not need to carry any significant heat flow from the interior of the planet, then the deep atmosphere is isothermal, and the temperature of the deep isothermal layer determines whether the atmosphere has a very deep condensing layer or no condensing layer at all. Note, however, that when the deep atmosphere is very optically thick in the infrared, it takes very little heat flux (and very little deep penetration of stellar radiation) to support a convective layer or a radiative layer with a strong vertical temperature gradient. This is the case, for example, in the atmosphere of Venus, for which most of the atmosphere remains near the CO$_2$ dry adiabat despite the feeble penetration of solar radiation to the surface.

Near the outer edge of the conventional habitable zone, CO$_2$ condensation becomes prevalent on planets which can maintain a substantial CO$_2$ inventory in their outer envelope, for example by volcanic outgassing from decomposition of carbonates in the deep interior of the planet. On the warm side of the outer limit, one would get non-dilute layers which do not reach the surface, as in figure 1. This situation would be expected in the CO$_2$-rich atmospheres of a warm, wet Early Mars or on a super-Earth like GJ581d [24] if made habitable by a massive CO$_2$ atmosphere.
If somewhat beyond the cold edge of the conventional habitable zone, such planets would instead develop CO\textsubscript{2} oceans or glaciers at the surface, with a non-dilute layer extending all the way to the condensible reservoir at the ground. In either case, non-diluteness would survive in the face of the addition of a moderate amount of non-condensible background gas such as N\textsubscript{2} or H\textsubscript{2}.

(ii) The ‘pure steam’ limit

Consider a substance which can undergo a phase transition from a gaseous (also known as vapour) phase to a condensed phase, which may be liquid or solid. Over a temperature range within which the latent heat $L$ of the phase transition can be considered constant, the Clausius–Clapeyron relation determining the phase boundary in pressure-temperature space implies

$$p_{c,sat} = p_1 \exp \left( \frac{-L}{R_c} \left( \frac{1}{T} - \frac{1}{T_1} \right) \right),$$

where $p_{c,sat}$ is the partial pressure of the condensible substance, $R_c$ is the ideal gas constant for that substance and $(p_1, T_1)$ is any point on the phase boundary. $p_{c,sat}$ is referred to as the saturation vapour pressure, or sometimes simply vapour pressure. The derivation of equation (3.2) also assumes the ideal gas equation of state and that the density of the condensate is much greater than the density of the vapour phase. The latter assumption breaks down near the critical point, as does the assumption of constant latent heat, since $L \to 0$ as the critical point is approached. Thus, equation (3.2) cannot be used near the critical point.

If the vapour phase is in contact with the condensed phase and comes into thermodynamic equilibrium with it, the partial pressure of the gas phase is $p_{c,sat}$. This contact could take the form of an interface with a macroscopic reservoir of condensate, such as an ocean or glacier, or it could take the form of contact with condensate interior to the atmosphere, such as a cloud, snow or rain particle. In saturated conditions, the partial pressure of the condensible, $p_c$ is equal to $p_{c,sat}$, so in the remainder of the exposition we will drop the extra subscripts when dealing with saturated conditions, when there is no risk of ambiguity.

Equation (3.2) can be solved for $T$ in terms of $p_c$ to yield

$$T_{sat}(p_c) = \frac{T_1}{1 - \Gamma \ln(p/p_1)}, \quad \Gamma = \frac{R_c T_1}{L},$$

where we have introduced the notation $T_{sat}$ to indicate the temperature obtained by solving equation (3.2) for temperature. This is the dew point or frost point formula (according to the nature of the condensed phase), which gives the temperature below which the condensible substance will form condensate, if given the chance to reach thermodynamic equilibrium. For an atmospheric temperature $T < T_{sat}(p_c)$, the atmosphere is supersaturated. An atmosphere that is sufficiently supersaturated will spontaneously form condensate, increasing temperature via latent heat release and reducing $p_c$ by conversion of vapour to condensed phase until $p_c$ is reduced to the saturation vapour pressure corresponding to the new, warmer temperature. In the presence of suitable condensation nuclei, little, if any, supersaturation is required to initiate the formation of condensate. On the other hand, if the atmospheric temperature is greater than the dew/frost point temperature, the atmosphere is subsaturated and condensate does not form.

If the condensible substance $c$ is the only gas present in the atmosphere, then the partial pressure $p_c$ is also the total atmospheric pressure $p$, so the temperature profile of a saturated atmosphere is simply $T_{sat}(p)$. This is the saturated moist adiabat for a single-component atmosphere, e.g. a pure water vapour atmosphere \cite[ch. 2]{8}. The Earth’s atmosphere, by contrast, contains a mixture of condensible water vapour with other gases that do not condense over the range of temperatures encountered in the atmosphere. Generalizing from the water vapour case, we shall refer to single-component condensible atmospheres as ‘steam atmospheres’. The definition of ‘condensible’ is relative to a planet’s climate, since any gas can be made non-condensible if the atmosphere is everywhere hot enough, and any gas can condense if made cold enough. The present CO\textsubscript{2}-dominated atmosphere of Mars would thus be considered a

close approximation to a steam atmosphere in our definition, as CO$_2$ condenses in the upper troposphere and in a deeper layer near the winter poles.

Because of the exponential growth of vapour pressure with temperature, an atmosphere with a non-condensable component will generally converge onto the steam atmosphere limit at high temperatures if the atmosphere is in contact with a sufficiently large reservoir of condensate, because the mass of condensable in the atmosphere increases, whereas the mass of the non-condensable gases remains fixed.

For steam atmospheres, the saturated moist adiabat giving temperature as a function of pressure has no free parameters, as the only constants in equation (3.3) describe thermodynamic properties of the gas. For mixed atmospheres containing a non-condensable component, the saturated moist adiabat contains a free parameter, namely the mass concentration $q_{a}$ of the non-condensable gas at some given pressure level. This allows the temperature at a reference pressure level $p_{0}$ to be chosen freely, subject to the constraint that $T(p_{0})$ be less than $T_{s\text{at}}(p_{0})$, at which temperature $q_{a} = 0$. As $T \rightarrow 0$, $q_{a} \rightarrow 1$. Once $q_{a}(p_{0})$ is known, the saturated moist adiabat is uniquely determined. For mixed atmospheres, the saturated moist adiabat is thus a one-parameter family of curves. $q_{a}$ is constrained by the total mass of non-condensable gas in the atmosphere, which must remain fixed, but this is a global constraint obtained by integrating over the entire atmosphere, and cannot be applied locally. By contrast, within any saturated layer of a pure steam atmosphere, the temperature is known once the pressure is known without any need to supply additional information.

$\Gamma$, shown for selected gases in Table 2 is typically a small number. According to equation (3.3), the temperature on the saturated pure steam adiabat varies only from $2T_{1}$ to $0.5T_{1}$ between pressures $p_{1}\exp(0.5/\Gamma)$ and $p_{1}\exp(-0.5/\Gamma)$ where $(p_{1}, T_{1})$ is the point on the phase boundary where $\Gamma$ is computed. This estimate is based on an assumption of nearly constant latent heat, as is equation (3.3), and so must be modified if the high-pressure and temperature end of the range approaches the critical point, where latent heat falls to zero. Even when the pressure is outside the range of relatively flat temperatures, the temperature approaches zero only gradually with height (like $1/\ln(p/p_{1})$, which is approximately like $1/z$ in altitude).

For dilute atmospheres, evaporation from the surface reservoir occurs whenever the overlying atmosphere is subsaturated. However, the lower boundary condition for non-dilute atmospheres works very differently, particularly as the pure steam limit is approached. To illustrate this point, we will consider a thought experiment involving an initially subsaturated atmosphere in contact with the surface condensed phase reservoir. Suppose the surface pressure in hydrostatic balance is $p_{s}$, as determined by the mass of the atmosphere. Then, subsaturation at the surface is defined by $T(p_{s}) > T_{s\text{at}}(p_{s})$. Let the temperature of the condensed reservoir be $T_{s}$, and suppose that $T_{s} = T_{s\text{at}}(p_{s})$, which is cooler than the overlying air temperature. In this case, the vapour pressure of the layer of vapour that forms immediately over the surface is identical to the pressure of the overlying air, $p_{s}$, and there is no unbalanced vertical pressure gradient to drive a bulk mass flow. However, since $T(p_{s}) > T_{s}$, radiative, diffusive or turbulent heat transfer will cause the lower portions of the atmosphere to cool until $T(p_{s})$ approaches $T_{s}$, forming a stable thermal boundary layer, within which $T(p)$ increases with height. This situation is illustrated schematically in Figure 2 for the case of an initially isothermal atmosphere. The entire layer will still be subsaturated, reaching marginal saturation just at the interface with the surface reservoir, so there will be no mass exchange with the reservoir in this situation. This contrasts with the more familiar situation.
Figure 2. Dashed line schematically shows adjustment to equilibrium of an initially isothermal subsaturated pure steam atmosphere over a condensate reservoir that is colder than the atmosphere, assuming the hydrostatic surface pressure of the atmosphere is continuous with the saturation vapour pressure corresponding to the ocean surface temperature. It is assumed the heat capacity of the surface ocean is enough to keep its temperature essentially constant in the course of the adjustment. Heat is transferred from the atmosphere to surface reservoir in the course of this process, but no mass exchange takes place.

Figure 3. Mass and temperature adjustment of an initially subsaturated isothermal atmosphere in contact with a condensate reservoir at the surface. In contrast with the case depicted in figure 2, in this case it is assumed that the hydrostatic pressure at the bottom of the atmosphere is less than the saturation vapour pressure corresponding to the surface temperature. (a) The initial state. The pressure discontinuity is eliminated by transfer of mass from the surface ocean to the atmosphere, which adds a layer of new atmosphere near the surface, thus increasing the surface pressure at the bottom of the atmosphere. New mass is added at a temperature following the pure steam adiabat, but the temperature at altitudes above the pressure level $p_0$ is not affected, leading to an adjusted profile with an inversion, as depicted in (b). Subsequent vertical heat transfer could erode the inversion, extending the subsaturated layer towards the surface.

In the dilute case, where one can have a subsaturated atmosphere with $T(p_s) = T_s$, requiring no heat exchange but allowing evaporation.

Mass exchange between the surface reservoir and the atmosphere is in fact determined by the vapour pressure $p_{\text{sat}}(T_s)$ relative to the hydrostatically balanced pressure $p_s$ given by the mass of the atmosphere. In a pure steam atmosphere, when $p_{\text{sat}}(T_s) > p_s$, a large unbalanced pressure gradient will develop near the surface, driving a rapid flow of mass from the condensate reservoir into the atmosphere, and correspondingly cooling the surface by evaporation. The increase in $p_s$ through the addition of mass, and the decrease in $T_s$ (and hence $p_{\text{sat}}(T_s)$) through evaporation will continue until the system comes into equilibrium with the pressure gradient eliminated, as depicted in figure 3 for an idealized thought experiment involving an initially isothermal atmosphere. Conversely, if $p_{\text{sat}}(T_s) < p_s$ the condensible vapour in contact with the surface will condense, releasing latent heat in the atmosphere, and the pressure gradient will rapidly carry more mass to the surface until equilibrium is restored.
In fact, even when the atmosphere consists of a mixture of a condensible and non-condensible component, the usual bulk formula for evaporative mass exchange between surface and atmosphere still implies that the exchange rate is proportional to the difference between $p_{\text{sat}}(T_s)$ and the partial pressure of the condensible in the overlying atmosphere [8, eqn. 6.13], which reduces to the above result in the pure steam limit. The only real difference between the condensible-rich case and the dilute case is that in the former the difference between $p_{\text{sat}}(T_s)$ and the condensible partial pressure is dynamically significant, and directly drives the flow which acts to restore equilibrium.

(iii) Basic nature of convection in non-dilute atmospheres

For a non-condensing (i.e. dry) atmosphere, a dry adiabat is established in the troposphere through buoyancy-driven mixing. With a condensible component, the situation is somewhat more complicated since condensation and latent heat release occur only for upward motions, but in the dilute limit the effect of latent heating in the upward plumes is communicated to the downward branches through compressive heating of the non-condensible gas which dominates the mixture, and loosely speaking the buoyancy-driven convection still mixes the profile towards a moist adiabat. In either case, buoyancy can be generated either by radiative heating and cooling in the interior of the atmosphere (when the radiative equilibrium is unstable to convection) or at the planet’s surface (if it has one) through absorption of stellar radiation there. Convection can also be sustained by heat flux from the planet’s interior, especially in the case of planets with a deep fluid layer such as Jupiter or Neptune in our own solar system, or fluid super-Earths such as GJ1214b. For non-dilute atmospheres, convection works very differently as the steam atmosphere limit is approached, in fact so differently it is unclear whether it should be called convection at all.

For an atmosphere with a non-condensible component, buoyancy can be generated because the moist adiabat has a free parameter; for example, stellar heating near the planet’s surface can set the boundary layer air to a hotter adiabat than that characterizing the free troposphere, so that once a parcel from the boundary layer is lifted to an altitude where condensation begins, further lifting will follow a saturated moist adiabat which will eventually render it buoyant with respect to its surroundings. As the atmosphere becomes increasingly non-dilute and all adiabats collapse onto the pure-steam adiabat, the ability to generate buoyancy disappears. In fact, the buoyancy referred to in the preceding discussion is just the thermal buoyancy corresponding to a situation in which condensate is instantaneously removed; the mass of retained condensate reduces buoyancy, and thus exerts a stabilizing effect which may be particularly important as the pure steam limit is approached.

As an illustration of the novel features of the strongly non-dilute case, consider a pure steam atmosphere above a condensate reservoir, and neglect all radiative heating and cooling of the atmosphere for the moment. Assume the pressure to be continuous with the surface vapour pressure. Barring supersaturation, the initial atmospheric temperature profile satisfies $T(p) \geq T_{\text{sat}}(p)$, and since lifted air parcels follow $T_{\text{sat}}(p)$ they will be negatively buoyant with regard to the environment wherever the environment is subsaturated, even if the lifted parcels immediately lose their condensate.

Suppose now that absorption of stellar radiation at the ocean surface causes the surface temperature to increase with time, so $T_s = T_s(t)$ is monotonically increasing. In a dilute atmosphere, this would create buoyancy and eventually deep convection. The corresponding surface pressure $p_{\text{sat}}(T_s(t))$ also increases monotonically with time, which via the hydrostatic relation corresponds to adding new mass at the bottom of the atmosphere, as illustrated in figure 4. In a pure steam atmosphere, this process proceeds without ever creating any buoyancy.

In pressure coordinates, there is no vertical motion associated with this process. Each new layer of atmosphere is slid into place at its own appropriate pressure as the boundary between atmosphere and ocean moves to higher pressures. Seen in altitude coordinates, there is vertical motion, since the existing atmosphere must be displaced upward to make room for the new
Figure 4. Sketch of evolution of a pure steam atmosphere in contact with a surface condensate reservoir whose surface temperature is increasing with time. The light- and dark-blue shaded regions indicate layers of vapour added to the atmosphere by evaporation from the condensate reservoir.

atmosphere that is added at the bottom, given that the vapour added has lower density and occupies more volume than the condensed phase removed from the ocean.

If one allows for net radiative cooling of the atmosphere, then the system can reach an equilibrium in which mass loss due to radiatively driven condensation aloft equals the mass added at the bottom of the atmosphere by evaporation. In this case, there is a net vertical motion in pressure coordinates, which gently lifts the moisture from the surface where it is added to the atmosphere to condensing levels aloft where it is removed, in a form of laminar moisture elevator. This motion is quantified in §3a(iv).

In the general non-dilute case that has not converged on the pure steam limit, there is some buoyancy generation and consequent convection, but the role of buoyant plumes is much less than that it is in the familiar dilute case. Parametrization of convection for general non-dilute atmospheres requires consideration of a number of additional factors that can be ignored in the dilute limit. Conservation of enthalpy in the course of mixing by convection needs to take into account the enthalpy, kinetic and potential energy carried by precipitation, and the portion of this energy associated with precipitation reaching the surface must be added to the surface energy budget. These effects are still somewhat significant even for the present Earth’s relatively dilute climate, and their neglect can lead to spurious imbalances in the top-of-atmosphere energy budget. In addition, loss of mass by precipitation causes a reduction in pressure in lower levels, which has both dynamical effects through horizontal pressure gradients and thermodynamic expects through adiabatic expansion to accommodate the pressure reduction. In [25], we have developed a simple convective adjustment scheme that can deal with the full range from dilute to steam atmosphere limits in an energetically consistent way, and used it to further discuss the behaviour of non-dilute convection.

(iv) Mass balance and Hadley circulations for non-dilute atmospheres

In primitive equation models, vertical velocity is diagnosed from the mass continuity equation. In the non-dilute case, the continuity equation needs be modified taking the mass loss due to precipitation into account. Let us consider the idealized case in which precipitation that forms is removed instantaneously to the surface (or to some deep layer of the atmosphere which we are not explicitly modelling). We may nonetheless allow for the possibility that some of the precipitation evaporates on its way down. Assuming the hydrostatic approximation,

$$\frac{\partial \rho \omega}{\partial t} + \nabla \cdot (\rho \mathbf{v}) = -(P - E),$$  (3.4)

where $\mathbf{v}$ is the horizontal velocity, $\omega$ is the vertical velocity of the gas phase in pressure coordinates, $P$ is the local rate of mass precipitation (positive being mass loss) and $E$ the local
evaporation rate, both per unit mass of the atmosphere. The idealization of instantaneous removal enters in an important way in this form of the continuity equation, since incorporating the effects of retained condensate would require one to write separate continuity equations for the gas phase and condensed phase; equation (3.4) would remain valid with \( p \) interpreted as total pressure, but \( \omega \) would represent only the rate of change in the hydrostatic pressure due to the gas phase and to be useful would have to be supplemented by a transport equation for the condensed phase.

Consider the idealized case of an ascending saturated plume in the pure steam limit, assuming that precipitation forms rapidly enough to prevent supersaturation, and that there is no re-evaporation on the way down (so \( E = 0 \)). \( P \) can be computed by determining the amount of latent heat that must be released to warm a parcel lifted along the non-condensing adiabat to the saturation temperature. By making use of the Clausius–Claperyon relation and the formula for the dry adiabat, we find

\[
\partial_t \omega \approx -\frac{RT_{\text{sat}}(p)}{Lp} \left( 1 - \frac{c_p T_{\text{sat}}(p)}{L} \right) \omega. 
\]  

(3.5)

The factor in parentheses multiplying \( \omega \) on the r.h.s. of equation (3.5) is positive for every plausible atmospheric gas we have checked, so long as one stays away from the critical point where the formulation becomes invalid. This implies that \( \omega \) has an exponentially decaying character with increasing altitude (decreasing \( p \)) and it is not hard to show that, on account of the \( 1/p \) factor on the r.h.s., \( \omega \to 0 \) as \( p \to 0 \). Thus, it is possible to satisfy the \( \omega = 0 \) boundary condition at the top of the atmosphere even if there is ascent \( \omega < 0 \) below.\(^1\) In contrast with the dilute case, in which ascent in a precipitating column must be balanced by subsidence in surrounding non-precipitating columns, the mass budget can be satisfied locally in an isolated ascending precipitating column. As the pure steam limit is approached, the familiar Hadley circulation collapses to a single column in which the upward mass flux of vapour is balanced locally by the downward mass flux carried by precipitation. Such a ‘Hadley cell’ does not transport heat, because heat transport in the familiar dilute Hadley circulation is mediated by compressional heating in the subsiding branch. As non-diluteness increases and the pure steam limit is approached, the subsidence and associated heat transport can be expected to weaken. Further, when the circulation collapses to a single column, it no longer transports angular momentum horizontally, and therefore does not engage the angular momentum balance, nor generate subtropical jets, in the way a true Hadley circulation does. In this degenerate limit, the dynamics is so different that the circulation can no longer be considered to be a Hadley cell at all.

An isolated ascending column corresponds to an atmospheric collapse solution. At the ground \( \omega = dp_s/dt < 0 \), implying a continual loss of atmospheric mass associated with precipitation reaching the ground. This is a perfectly valid solution for any value of \( \omega(p_s) \), and additional physical processes must be brought into the picture to remove the degeneracy and fix a unique equilibrium solution. For example, evaporation from the surface reservoir would generally adjust until the rate of adding mass at the bottom of the atmosphere equals the mass loss due to precipitation; in a model, this would typically be implemented as a thin layer of negative precipitation at the bottom, within which \( \omega \) adjusts from its negative value aloft to zero at the ocean interface. In a two- or three-dimensional circulation, mass could also be resupplied by horizontal convergence.

Integrating equation (3.4) vertically over the whole depth of the atmosphere yields an equation for the evolution of the surface pressure identical to the usual one except for the introduction of pressure change due to vertically integrated \( P - E \). When implementing a general circulation model, this precipitation term, and the corresponding one in equation (3.4), only needs to be taken explicitly into account for large-scale precipitation. For convective precipitation, the effect of precipitation on \( \omega \) is implicitly taken into account as part of the re-labelling of pressure levels that is generally necessary in a non-dilute convection parametrization, as discussed in [25].

\(^1\) The equation becomes inconsistent if there is subsidence, because precipitation happens only on ascent; negative precipitation on subsidence would require the presence of enough retained condensate to sustain evaporation in the subsiding air mass.
When computing the geopotential $gZ$ from the hydrostatic relation, care must be taken in non-dilute atmospheres to account for the effect of the condensable on atmospheric density. This is a straightforward modification, which is already incorporated in many conventional general circulation models through use of a virtual temperature, though in many cases diluteness is assumed when computing the modification of density due to water vapour.

(v) Barotropic nature of strongly non-dilute circulations

Section 2 shows that the atmospheres of slowly rotating planets are generally expected to exhibit weak horizontal temperature gradients regardless of their diluteness. It is abundantly clear that dilute atmospheres on rapid rotators support strong temperature gradients, as in Earth’s extratropics. What is the situation for non-dilute rapid rotators?

For sufficiently rapid rotators, the atmospheric flow will be in geostrophic balance. For geostropically balanced flow, the thermal wind relation links vertical gradients in wind to horizontal density gradients taken on an isobaric surface. Specifically introduce a local Cartesian coordinate system $(x, y)$ on a pressure surface, and let $u$ be the wind in the $x$-direction. Then the thermal wind relation states

$$\partial_p u = \frac{1}{pf} \partial_y \bar{R}T |_p, \quad (3.6)$$

where $\bar{R}$ is the gas constant for the mixture of condensible and non-condensible gases at each point and $f$ is the local Coriolis parameter. However, we know that in the saturated steam atmosphere limit, $T = T(p)$, i.e. temperature is uniform on isobaric surfaces within the saturated part of the atmosphere. Moreover, in a pure steam atmosphere $\bar{R} = R_c = \text{const.}$, equation (3.6) then implies that the wind is independent of height, and that the dynamics is barotropic. Figure 5, which gives the saturated moist adiabat for a family of atmospheres with a non-condensible component, shows that as temperature increases and the atmosphere becomes increasingly non-dilute, all the adiabats collapse onto the pure-steam adiabat. In consequence, strongly non-dilute saturated atmospheres will tend to have nearly barotropic dynamics. They will have weak horizontal temperature gradients on pressure surfaces, even if the planet rotates rapidly.

Note that the above result assumes saturation. Strongly subsaturated atmospheres, even if pure steam, can be baroclinic. Hence the factors determining subsaturation also have a major effect on the dynamics of the atmosphere. We will see some examples of the behaviour of subsaturation in three-dimensional non-dilute atmospheres in §5d.
Figure 6. Latitude-height profile of a barotropic atmosphere with a non-zero surface temperature and pressure gradient.

The barotropic nature of the system does not in itself preclude the existence of strong temperature gradients at the planet’s surface (if it has one), because the planetary surface is not an isobaric surface. The surface pressure gradients are equal to the pressure gradients aloft, and geostrophically balance the barotropic winds. Differential stellar heating of the planet’s surface would lead to surface temperature gradients, just as the Earth is generally colder at the poles than at the equator. On a planet with a surface condensible reservoir, these temperature gradients would lead to corresponding surface pressure gradients via the Clausius–Clapeyron relation. The situation is situated in figure 6.

In a dilute rapidly rotating atmosphere like the Earth’s, baroclinic instability acts to weaken temperature gradients in midlatitudes and the Hadley cell weakens them in the tropics. For the saturated strongly non-dilute case, the dynamics is barotropic, so baroclinic eddies cannot play a role in transporting heat. Hadley cells are also unable to transport heat efficiently in non-dilute atmospheres, for the reasons discussed in §3a(iv). However, there are a number of other mechanisms that can act to wipe out surface temperature and pressure gradients in a non-dilute atmosphere.

(b) Mechanisms of horizontal homogenization of temperature

(i) Barotropic adjustment

Suppose that differential stellar heating of a planet gives rise to a latitude-dependent surface temperature $T_s(\phi)$ (figure 6). On a planet with a global surface reservoir of condensible, this will give rise to a surface pressure $p_s(\phi) \approx p_{sat}(T_s(\phi))$ if the planet is warm enough for the atmosphere to be dominated by the condensible. Because of the exponential dependence of saturation vapour pressure on temperature, a small surface temperature gradient translates into a large surface pressure gradient, and hence (by geostrophic balance) a very large barotropic wind. Unless the temperature gradient is sufficiently small, the resulting jet will be barotropically unstable, and the resulting instability will act to weaken the jet and to redistribute mass such that the surface pressure and temperature gradients weaken.

The assumption that barotropic instability acts to adjust the state to one of barotropic neutrality can be used to obtain an estimate of the surface pressure and temperature gradient towards which the system is relaxing. Introduce a local Cartesian coordinate $y$ in the vicinity of latitude $\phi_0$, measuring distance in the meridional direction. Let $u(y)$ be the zonal wind in a geostrophically balanced state. Then according to the Rayleigh–Kuo criterion neutrality to barotropic instability requires

$$
\beta - \frac{d^2 u}{dy^2} = 0,
$$

(3.7)
where $\beta \equiv (df/df)(\phi_0) = 2(\Omega/a)\sin \phi_0$. Geostrophy and Clausius–Clapeyron imply

$$u = -\frac{1}{f_0 \rho} \frac{dP_{\text{sat}}}{dy} = -\frac{1}{f_0} L \frac{1}{T_s} \frac{dT_s}{dy}. \tag{3.8}$$

If we stipulate that winds are weak near the poles, equation (3.7) implies $u \sim \beta a^2$, where $a$ is the radius of the planet. Further, the planetary scale temperature variation is $\Delta T_s \sim a (dT_s/dy)$. Substituting into equation (3.8) and solving for the temperature variation yields

$$\frac{\Delta T_s}{T_s} \sim \beta f_0 a^3 \frac{1}{L} \sim \frac{\Omega^2 a^2}{L}. \tag{3.9}$$

Therefore, the constraints imposed by barotropic stability only guarantee WTGs for slow rotators; sufficiently rapid rotators can support large temperature gradients in strongly nondilute atmospheres without the corresponding jet becoming barotropically unstable. Because the latent heat $L$ is typically a large number, however, weak gradients can prevail up to quite large values of $\Omega a$. For example, for an Earth-sized planet with half the Earth’s rotation rate, a saturated pure water vapour atmosphere would have $\Omega^2 a^2/L = 0.021$, corresponding to roughly a 2% relative variation in surface temperature. The expression in equation (3.9) is similar in form to the parameter $\Lambda^{-2}$ which is small when the WTG approximation is valid, except that $RT$ is replaced by $L$. Since $L \gg RT$ away from the critical point of the atmospheric gas, the barotropic adjustment process in a saturated pure steam atmosphere can maintain WTGs at higher rotation rates than would be possible in the absence of condensation.

(ii) Ekmanspin-down

For planets with a surface which exerts frictional drag on the overlying atmosphere, Ekman spin-down offers another way of damping surface pressure and temperature gradients. Surface temperature gradients induce surface pressure gradients via Clausius–Clapeyron, and these gradients are in turn balanced by a geostrophic wind. Within the frictional boundary layer, the dominant balance between frictional forces on the wind and the Coriolis force induces a drift in the boundary layer in the direction from high pressure to low pressure, as illustrated in figure 7. Alternatively, the process can be understood in terms of the ‘Einstein’s Teacup’ analogy, in which the pressure gradients in the boundary layer are nearly the same as in the geostrophically balanced atmosphere aloft, but friction has weakened the wind that induces the balancing Coriolis forces, thus leaving an unbalance pressure gradient that drives a downgradient current. With either way of looking at it, the process spins down the wind, transports heat and mass towards cold regions, and acts to damp the surface pressure and temperature gradients.

For an Earth-like fast-rotating planet, the Ekman layer is thin enough that the atmospheric temperature in the layer is close to the surface temperature ($T_s$). Then the energy balance of the planetary system (ignoring heat flux in the ocean) at latitude $\phi$ can be simplified as

$$S_{\text{abs}}(\phi) - \text{OLR}(T_s(\phi)) \approx \frac{1}{a \cos \phi} \frac{d}{d\phi} (\cos(\phi) M_{\text{E}}(\phi)L(T_s)), \tag{3.10}$$

where $S_{\text{abs}}$ is the absorbed stellar flux, OLR is the outgoing longwave radiation of the planetary system, $a$ is the radius of the planet, $M_{\text{E}}$ is the meridional Ekman mass transport and $L$ is the specific latent heat of vaporization (assumed to have a weak temperature dependence). The l.h.s. of equation (3.10) represents the net downwelling radiative flux at the top of the atmosphere and the r.h.s. represents the divergence of the meridional energy flux. Assuming that friction in the Ekman layer is parametrized by a constant eddy viscosity $A$, $M_{\text{E}}$ can be described by the product of the layer thickness and the geostrophic zonal wind [26, p. 112], and then is related to
the meridional gradient of surface temperature through the Clausius–Clapeyron relation

\[
M_E \approx \frac{1}{2} \sqrt{\frac{A}{\Omega \sin \phi}} \frac{1}{2 \Omega a \sin \phi} \left( -\frac{dp_{\text{sat}}(T_s)}{d\phi} \right)
\]

\[
= \frac{1}{2} \sqrt{\frac{A}{\Omega \sin \phi}} \frac{1}{2 \Omega a \sin \phi} \left( \frac{Lp_{\text{sat}}(T_s)}{RT_s^2} \right) \left( -\frac{dT_s}{d\phi} \right),
\]

where \( \Omega \) is the spin rate of the planet. The final equality proceeds from application of the chain rule and Clausius–Clapeyron. Furthermore, the OLR of a steam atmosphere is nearly a linear function of \( T_s \) before the runaway greenhouse occurs. With the above simplifications, equation (3.10) becomes the equation of a diffusive energy balance model with a latitude-dependent diffusivity. The steady-state meridional distribution of \( T_s \) can be obtained by solving such a diffusion equation numerically given the insolation profile.

We can simplify equation (3.10) further if considering the limit in which the horizontal energy transport is so efficient that the global surface becomes isothermal (denoted as \( T_{s0} \)),

\[
S_{\text{abs}}(\phi) - \text{OLR}(T_{s0}) \approx \frac{1}{a \cos \phi} \frac{d}{d\phi} (\cos(\phi)M_E(\phi)L(T_{s0})) = (E - P)_{(\phi)}L(T_{s0}),
\]

(3.11)

where \((E - P)\) is the net evaporation rate at the surface \((E\) represents the evaporation and \(P\) the precipitation\) and is proportional to the net radiative flux at the top of the atmosphere. This implies the condensible substance goes from the surface reservoir to the atmosphere in the low-latitudes, and returns to the reservoir again in the high-latitudes.

In §5b, we will show simulations demonstrating the effectiveness of this mechanism for equalizing surface pressures and temperatures in non-dilute atmospheres.

(c) Inhibition of subsaturation for strongly non-dilute flow

Much of the discussion of the novel behaviour of non-dilute atmospheres relies on the assumption that nearly saturated conditions prevail within extensive regions of the atmosphere. In the Earth’s present dilute atmosphere, by contrast, most of the atmosphere is highly undersaturated, even in the free troposphere over the oceans. In the Earth’s dilute atmosphere, subsaturation is produced primarily through transporting moist air parcels to colder, lower pressure places (poleward or
aloft) where adiabatic expansion and other cooling mechanisms cause most of the condensable substance to rain out, and then transporting them back to higher pressure warmer places where the warming increases the saturation vapour pressure of the parcel but not the condensable content (until it picks up a new supply of condensable from some source) [27]. This can happen at the scale of baroclinic synoptic eddies in midlatitudes, or on global scales due to planetary Rossby waves in the midlatitudes or Hadley and Walker circulations in the tropics. It can also happen at the scale of ensembles of convective clouds.

There are a number of factors that make it much harder for strongly non-dilute atmospheres to generate significant subsaturation. Once a saturated layer is established in such an atmosphere, the dynamics becomes largely barotropic, as discussed in §3a(v), which precludes the vertical motions needed to generate subsaturation. Thus, saturated layers tend to maintain themselves in strongly non-dilute atmospheres. Further, the mass-flux in the upward branches of Hadley and Walker circulations do not need to be fully compensated by subsidence in the surroundings in strongly non-dilute atmospheres, as the upward flux of vapour is mostly balanced in situ by the downward mass flux associated with precipitation (§3a(iv)). In dilute atmospheres with extensive tropical circulations, the large-scale subsidence which brings down dry air from the upper troposphere is a key source of subsaturated air [27].

More generally, subsaturation is difficult to produce in strongly non-dilute atmospheres because a significant isobaric gradient in subsaturation between neighbouring air parcels requires a gradient in temperature, since in the pure steam limit the degree of saturation corresponds to the excess of temperature over $T_{\text{sat}}(p)$. By contrast, for a dilute atmosphere, a saturated air parcel can have the same temperature (more precisely the same virtual temperature) as a neighbouring completely dry parcel. In a non-dilute atmosphere, the temperature gradients associated with a subsaturation contrast extending over a deep layer would lead to strong pressure gradients in accordance with hydrostatic balance. This would drive circulations that tend to mix away the gradient. By itself this only implies weak gradients in degree of subsaturation, but if there is any portion of the atmosphere that is maintained near saturation (e.g. in a region of strong non-dilute convection), the saturation there will tend to be transmitted to the rest of the atmosphere.

The preceding effects inhibit dynamic production of subsaturation of the type that occurs in the Earth’s troposphere, but subsaturated layers can nonetheless be produced by radiative means in a non-dilute atmosphere. Any layer of the atmosphere within which the local radiative equilibrium $T_{\text{r.e.}}(p)$ exceeds the saturation temperature $T_{\text{sat}}(p)$ will be subsaturated. Such layers would typically be produced by strong absorption of shortwave stellar radiation by the atmosphere, and if the atmosphere is so strongly absorbing that essentially no shortwave radiation reaches the surface, the subsaturated layer can even extend all the way to the condensed reservoir at the surface. Note that the stellar heating need not be strong enough to create a temperature inversion. Temperature can decrease with height, so long as it does not fall below $T_{\text{sat}}(p)$. If the atmosphere is very optically thick in the infrared, however, even a trickle of shortwave radiation reaching the surface would heat the surface enough to be warmer than the overlying radiative-equilibrium temperature, leading ultimately to a saturated precipitating layer extending upward from the surface.

Although the above arguments lend a certain plausibility to the assertion that atmospheres should become more saturated as they become more non-dilute (barring effects of strong internal radiative heating), the dynamical issues are subtle and difficult to quantify convincingly without some guidance from full three-dimensional simulations. We will return to the issue of subsaturation in §5d.

4. Description of the exo-FMS model

We have developed an idealized three-dimensional general circulation model (GCM) with simplified physical parametrizations including an active hydrological cycle based on formulations that remain valid regardless of the diluteness of the condensable substance in the
atmosphere. It is a variant of the model used to study idealized atmospheres in [28,29] and the model used to study tidally locked Earth-like aquaplanets in [30]. These models are designed to improve our understanding of fundamental processes in complex planetary atmosphere, and are different from the models of a high degree of complexity used for making precise predictions.

Two major modifications are made in our model compared with previous studies. First, to avoid numerical instabilities at high concentrations of the condensable substance, our model (hereafter referred to as exo-FMS) uses the finite-volume dynamical core of the GFDL flexible modelling system (FMS) described in [31] instead of the spectral transform method used in [28,30] to solve three-dimensional primitive equations of an ideal-gas atmosphere. Second, exo-FMS uses an energy-conserving simplified moist convection scheme without any approximation about the diluteness of the condensable substance while conventional GCMs usually use the dilute approximation and assume the surface pressure and thermodynamic parameters of the atmosphere is insensitive to the amount of condensible substance in the atmosphere. Our moist convection scheme is similar in spirit to the hard convective adjustment scheme in [32], but conserves non-dilute moist enthalpy while the condensate is produced and retained in the atmosphere, and takes the energy change due to mass redistribution into account when the condensate falls to the surface or enters the atmosphere through surface evaporation. The condensate falls within the same time step right after it is produced in the super-saturated layer. The non-dilute moist convection scheme is described and validated in [25], where we show that it conserves both energy and mass from the dilute to non-dilute regime. Similarly, our large-scale condensation scheme takes into account the conservation of non-dilute moist enthalpy and the energy loss associated with large-scale condensation precipitation. Microphysical effects are no doubt of considerable importance in all planetary atmospheres with a condensible component, but in these simulations we neglect the microphysics governing formation and removal of precipitation, as well as effects of retained condensate and atmospheric heating due to frictional dissipation surrounding falling precipitation.

Since we wish to highlight dynamical phenomenon in this paper, the exo-FMS simulations presented here use a grey radiation scheme in the infrared spectral region, and assumes the atmosphere is transparent to shortwave radiation. The longwave optical depth $\tau$ has two contributions

$$\tau(p) = \kappa_0 \int_0^p q(p') \frac{dp'}{g} + \tau_1 \frac{p}{p_s},$$

where $\kappa_0$ and $q$ are the absorption cross-section and the mass concentration of the condensable substance, respectively, and $\tau_1$ is the total optical thickness of the non-condensable absorber which is assumed to be well mixed in the atmosphere. Both $\kappa_0$ and $\tau_1$ are constants. In the simulations, we present in this paper, $\tau_1$ and $\kappa_0$ are independant of the total mass of non-condensable in the atmosphere. This is somewhat unrealistic since it assumes the total mass of the non-condensable greenhouse gas decreases with $p_s$ in such a way as to compensate for pressure broadening and keep $\tau_1$ fixed, and also neglects pressure broadening or collisional opacity of the condensable component. However, this experimental protocol allows us to keep the mean surface temperature roughly fixed as the mass of the non-condensable background is changed, and thus makes it easier to isolate the effects of non-diluteness. For similar reasons, we avoid the complex issues associated with cloud feedbacks by neglecting the radiative effect of clouds.

The opposite regime from the shortwave-transparent atmospheres we consider in the present work is the one in which atmospheric shortwave absorption is so strong that essentially all incoming stellar radiation is deposited directly in the atmosphere, rather than being deposited at the ground and being communicated upwards by radiation and convection. Many exoplanets, including low-density super-Earths such as GJ1214b, are expected to be fluid planets with no distinct surface at all. Planets without appreciable deposition of stellar energy at a distinct surface can nonetheless have non-dilute layers, as discussed in §3a(i). This is an important regime, which will be the subject of future work.

In exo-FMS, the specific heat capacity of the substances in the atmosphere are treated as constants, but the specific latent heat of vaporization has a weak temperature dependence.
Figure 8. Cross section of the atmospheric temperature (K) along anti-stellar longitudes (a) and substellar longitudes (b) of a tidally locked simulation conducted in the dilute regime. Averages are taken over $10^3$ of longitude.

The specific latent heat of a material varies approximately linearly with the temperature when the density of the condensate is much greater than that of its vapour phase [33, p. 115].

\[
\frac{dL}{dT} \approx c_{pc} - c_{pt}.
\]

Here $c_p$ is the specific heat capacity at constant pressure, and subscript ‘c’ and ‘t’ represents the vapour phase and the condensate, respectively. With this form of temperature dependence, it is fairly straightforward to formulate a moist enthalpy incorporating both gaseous and condensed phases, which is conserved when the enthalpy carried by precipitation is taken into account. For simplicity, there is only a single-phase transition in exo-FMS, which could equally be interpreted as liquid–vapour or ice–vapour.

The lower boundary of the column model is a liquid slab ocean with uniform thickness. At the surface, the sensible and latent heat fluxes are computed based on the bulk exchange formulae [8, p. 396] assuming constant drag coefficient ($C_D = 0.005$). The surface pressure is calculated not only by the air flow divergence above the ground as in conventional GCMs, but also by the $(E - P)$ flux at the surface. In the surface energy budget, other than the sensible and latent heat fluxes and the radiative flux, we also take into account the internal and potential energy flux of the exchanged mass between the atmosphere and the surface reservoir to conserve energy. In exo-FMS, both the mass of the non-condensable and condensable substances (including both phases in the atmosphere and surface reservoir) are conserved. The former conservation is automatically achieved by the FMS finite-volume dynamical core. The mass budget of the slab ocean requires a mass redistribution scheme to even out the horizontal variations of the ocean depth created by the distribution of $P - E$. Otherwise, the liquid substance will accumulate in some places and be depleted in other places. At each time step, mass is redistributed so as to keep the ocean depth globally uniform, and then a globally uniform temperature offset is applied to the ocean temperature so as to enforce conservation of oceanic energy in the course of the mass adjustment. The oceanic heat transport implied by the temperature adjustment is small, because it is only the heat associated with the mass added to or taken away from an ocean column that is mixed throughout the global ocean, leaving the pre-existing temperature gradients intact. Details of the adjustment scheme, as well as other technical details concerning the formulation of exo-FMS, are provided in the electronic supplementary materials.

To show that exo-FMS is capable of reproducing features familiar from other moist simulations of circulation of tide-locked planets, we will show one dilute tidally locked simulation with...
experimental design essentially identical to those described by Merlis & Schneider [30], except that the period of the circular orbit is taken to be 50 Earth days. Two latitude-height cross sections of temperature are shown in figure 8. Exo-FMS reproduces the WTG behaviour (fig. 9 in [30]) in the free troposphere. In our simulation, the horizontal temperature gradient is small aloft both on the dayside and nightside of the planet. Other familiar features include the shallow hot-spot in the lower atmosphere over the substellar point, and the nightside temperature inversion near the surface. Horizontal winds, vertical velocity and precipitation are shown in figure 9, and reproduce the typical features of strong low-level convergence into a region of concentrated updraft and precipitation near the substellar point, with subsidence aloft over most of the planet. Aloft, the simulation reproduces the familiar equatorial super-rotating winds and the global Kelvin/Rossby wave pattern expected in a planet with weak but non-vanishing rotation.

Figure 9. (a) Five hundred hectopascal horizontal winds (arrows) and vertical pressure velocity $\omega$ (arrow colours) for the dilute tidally locked simulation. (b) Nine hundred hectopascal winds (arrows) and net column precipitation (colour shading). The grey circle marks the substellar point.
5. Three-dimensional simulations of non-dilute atmospheres on rapid rotators

(a) Simulation design

Since the novel effects of non-diluteness are most striking in the case of rapid rotators, we concentrate on that case here. Hot tide-locked planets in short-period orbits can be rapid rotators, but we will also focus here on Earth-like annual mean instellation patterns, which are symmetric about the rotation axis. For tide-locked planets, whether slowly or rapidly rotating in the sense of the WTG approximation, non-diluteness is expected to cause interesting and important deviations from the dilute pattern consisting of subsaturated subsiding air over most of the planet, but that will be the subject of a future paper.

Our simulation design is similar to the study of the runaway greenhouse state of a three-dimensional grey atmosphere in [34], except we have performed simulations with a range of values of the inventory $p_{a0}$ of the non-condensible gas. The non-condensible inventory is the parameter we vary in order to control the diluteness of the atmosphere. An alternative way to control diluteness is to keep $p_{a0}$ fixed but vary the instellation of the planet (corresponding to changing the luminosity of the star or the radius of the orbit), but varying $p_{a0}$ makes for a cleaner exploration of non-diluteness effects because the maximum surface temperature remains approximately fixed in our simulation. All other parameters are chosen to mimic the present Earth conditions. The non-condensable substance in the simulation is mixed N2–O2 air, as in the present Earth’s atmosphere, while the condensable substance is water vapour. As in [34], the longwave absorption cross-section of water vapour $\kappa_0$ is a constant, $0.01 \text{ m}^2 \text{ kg}^{-1}$. The atmosphere is transparent to the shortwave incoming radiation and the surface albedo is zero.

The top-of-atmosphere instellation is given by the annual and zonal average evaluated with the present Earth’s orbit, approximated by

$$S_{\text{TOA}}(\phi) = S_0 (1 + 0.3(1 - 3 \sin^2 \phi)),$$

where $S_0 = 300 \text{ W m}^{-2}$ is the global mean insolation and there is no diurnal or seasonal cycle. The horizontal resolution used in this study is $144 \times 96$, and there are 40 unevenly spaced vertical levels in hybrid $\sigma = p/p_s$ coordinate (pressure $p$ and surface pressure $p_s$). The pressure of the radiative level in a pure water-vapour atmosphere in our model is 9.8 hPa. Given that the strongest radiative cooling and convective heating of water vapour occurs near the radiating level, the pressure at the top of our model is chosen to be 0.01 hPa in order to resolve the radiative and convective processes in the non-dilute atmosphere.

As listed in table 3, four experiments are presented with different values of non-condensible inventory $p_{a0}$. Each experiment is referred to as a letter P followed by the value of $p_{a0}$ in hPa specified in the experiment. Experiment P1000 is the run that mimics the present Earth’s atmosphere. The results we present are averages over the last 600 days of 3000-day integrations.

Because the mass of dry air in our experiments has no direct radiative effect, the global mean $T_s$ varies only by 7 K$^3$ (table 3). Hence, it is primarily the mass of dry air that alters the concentrations of water vapour in the atmosphere by two orders of magnitude. Though we vary the partial pressure of the non-condensible gas in these simulations primarily as a convenient means of controlling non-diluteness, there are in reality many real physical processes that can enter into the determination of the non-condensible inventory on actual planets, so exoplanet climate studies should always consider a wide range of possible values for this parameter. For our own planet Earth, a surface pressure of two or three times the present value is proposed to help reduce the amount of CO2 needed to resolve the ‘Faint Young Sun’ paradox, via pressure-broadened increase of infrared absorption of greenhouse gases [35] or the H2–N2 collision-induced absorption [19],

---

2 An average angle should be taken into account in the two-stream radiation equations because the infrared flux tends to become forward-peaked as it propagates. Our chosen $\kappa_0$ has already include this effect. This is slightly different from the radiation scheme used in [34], who do not specify the average angle they chose.

3 There is an indirect radiative effect through the effect of the dry air on the lapse rate, and through nonlinear rectification of surface temperature variations in latitude.
Table 3. The list of experiments and the values of the initial surface partial pressure of the $\text{N}_2$-$\text{O}_2$ air ($p_{\text{a}}$), global mean surface temperature ($T_s$) and global mean mass concentration of water vapour in the atmosphere $q$ for each experiment.

though fossil raindrop imprints suggest an absolute upper limit of less than 2100 hPa for the late-Archean climate [36]. The mass of the non-condensable on Earth-like exoplanets is even more difficult to constrain by transit spectra. The mass of the non-condensable can affect the planetary climate through various ways, and our study here only focuses on diluteness effects.

(b) Basic description of zonal-mean temperature and humidity fields

The zonal mean temperature fields in the simulations are shown in figure 10a–d, and the specific humidity fields (figure 10e–g) provide an indication of the degree of diluteness of the atmosphere in each simulation. The most dilute experiment, P1000, exhibits a latitude-height pattern of temperature and humidity similar to the Earth’s present atmosphere, with WTG behaviour seen only in the tropics. As the atmosphere is made more non-dilute, the vertical temperature gradients become weaker; this is a simple consequence of the flatness of the moist adiabat, and its tendency to become nearly isothermal as the steam atmosphere limit is approached, as discussed in §3a(ii). The temperature gradient on isobaric surfaces also becomes weaker, as expected from the discussion in §3a(v). Moreover, the planet’s surface becomes nearly isobaric (and hence nearly isothermal), as argued in §3b. Specifically, the equator-to-pole surface temperature differences in the four experiments reduce from 40 K in P1000 to 1 K in P0.

Note that even in the very non-dilute case P5, the low-level specific humidity varies by nearly 25%, with the lowest values appearing in the polar regions. This may be surprising in view of the WTGs, but it is a simple consequence of the fact that the exponential dependence of vapour pressure on temperature makes the specific humidity very sensitive to temperature in cases with just a small amount of non-condensible gas.

(c) The nature of the circulation

Latitude-height profiles of zonal mean wind are shown in figure 11a–d, with corresponding meridional circulation shown in figure 11e–h. The streamfunctions are computed using only the large-scale velocity, and not the convective mass transport of condensible implicit in the convection parametrization, which is balanced by the mass flux of precipitation. For experiment P1000, which has Earth-like diluteness, there are baroclinic jets associated with midlatitude temperature gradients. Detailed examination of the transient eddy properties is beyond the scope of this work, but an examination of the time behaviour (not shown) reveals Earth-like midlatitude baroclinic eddies and eastward-propagating convectively coupled waves in the tropics. There is a strong Hadley circulation. This only appears shallow because of the large range of pressures plotted; it in fact reaches to approximately 200 hPa. Associated with this circulation is a pair of strong subtropical jets. These subtropical jets are somewhat more strongly separated from the midlatitude jets than is generally the case in the Earth’s present climate, but that may be due to the aquaplanet configuration.

At the other extreme, in the pure steam simulation there is essentially no horizontal temperature gradient in the interior of the atmosphere. In accordance with §3a(v), the vertical zonal wind shear vanishes and two barotropic jets emerge at approximately 60° (experiment P0,
Figure 10. Zonal-mean cross sections of the temperature (K) in experiments (a) P1000, (b) P30, (c) P5 and (d) P0, and the mass concentration of water vapour (kg kg\(^{-1}\)) in experiments (e) P1000, (f) P30 and (g) P5. The concentration of water vapour in experiment P0 is unity everywhere in the atmosphere, and therefore is not shown in the figure. The plots of temperatures share the same contour intervals. The white horizontal bars at the bottom of the atmosphere are due to meridional surface temperature variations when the atmosphere becomes non-dilute.
Figure 11. (a–d) Zonal-mean cross sections of the zonal wind component (m s\(^{-1}\)) in experiments (a) P1000, (b) P30, (c) P5 and (d) P0. (e–h) Same as panels (a–d), but for the zonal-mean cross sections of the mass streamfunction in 10\(^9\) kg s\(^{-1}\) in each experiments.
The jets are weak and barotropically stable, and in fact the system settles into a time-independent state with no transient eddies at all. This suggests that the surface pressure gradients are being determined by the Ekman transport mechanism rather than barotropic adjustment, which would proceed via barotropic instability. The Hadley cell has completely vanished, and meridional mass transport is dominated by boundary layer currents which carry mass from the high-pressure tropics to the low-pressure poles.

The pure steam simulation illustrates a striking effect of non-diluteness on the angular momentum budget of the planet. In this simulation, the low-level flow is everywhere poleward and maintains surface winds that are westerly everywhere. At first glance, this appears paradoxical, because the resulting unbalanced torque would spin up the planet without bound, violating angular momentum conservation. The resolution relates to the angular momentum carried to the surface by precipitation. The everywhere-poleward mass flux, which would be impossible in a dilute atmosphere, is possible in this case because the atmosphere picks up mass through evaporation in the tropics and loses it by precipitation at higher latitudes. The coriolis force acting on this current maintains the global surface westerlies against friction. The mass added to the atmosphere in the tropics takes high angular momentum with it. As air parcels move poleward, their angular momentum reduces through the action of friction. Thus, when mass is returned to the surface by precipitation, it has lower angular momentum than when it left the surface in the tropics. This acts as a sink of angular momentum of the surface ocean, compensating the net torque exerted on it. In experiment P0, the global mean value of the angular momentum source and sink are estimated as $5.49 \times 10^4$ and $5.60 \times 10^4$ N m$^{-2}$, respectively, which very nearly closes the angular momentum budget.

In the intermediate cases P30 and P5, the main surprise is that the vertical wind shear is quite strong, despite the weakening horizontal temperature gradients. In fact, the maximum jet speed actually increases between the Earth-like case and the more non-dilute case P30. This behaviour arises in part because the thermal wind relation (equation (3.6)) has a pre-factor $p^{-1}$ which tends to amplify the vertical shear (as seen in pressure coordinates) when the pressure is low. The rest of the behaviour is due to a novel dynamical effect of moisture in the non-dilute regime. In a dilute atmosphere, the gas constant $R$ in equation (3.6) is nearly constant. It is also constant in the pure steam limit. However, in non-dilute atmospheres that are not close to the pure steam limit, $R$ varies greatly in the horizontal because the variations of specific humidity lead to variations in the mean molecular weight of the atmosphere. Recall that $R = R^*/M$, where $M$ is the mean molecular weight. Since the simulations were done with dry air (molecular weight 29) as the non-condensible and water vapour (molecular weight 18) as the condensible, the lower specific humidity towards the poles in cases P30 and P5 leads to higher mean molecular weight and lower $R$ in polar regions, yielding an effect analogous to decreasing temperature poleward with fixed $R$. The effect could be captured in the conventional form of the thermal wind relation by defining a virtual temperature $T_v$ such that $RT = R_d T_v$, where $R_d$ is the gas constant for the non-condensible background atmosphere. Note that the sign of the compositional thermal wind would be reversed if the condensible had higher molecular weight than the background, e.g. for condensible H$_2$O or CO$_2$ in non-condensible H$_2$. In such situations, the moderately non-dilute climates would exhibit weaker or even easterly vertical shear.

The intermediate diluteness cases exhibit a Hadley cell of the classic form, but it gets wider, deeper (as measured by range of pressure it covers) and weaker as the non-diluteness is increased. The depth increase results from the elevation of the tropopause, which in turn is associated with the weak lapse rate associated with hot moist adiabats. The causes of the broadening are more subtle and require further analysis, which we will not pursue here.

Unlike the pure steam case, the intermediate diluteness cases do exhibit transient eddies. In case P5, the transience consists of fairly large-scale convective clusters that appear and disappear without any clear propagation. Though there is some eddy activity in the midlatitudes, this is largely barotropic and almost all precipitation in case P5 is convective precipitation associated with the tropical convective clusters. It is interesting that the compositional meridional baroclinicity does not give rise to baroclinic instabilities. This may arise because ascending,
condensing motions do not alter the mass distribution, while non-condensing descending motions expend energy in subsiding through a statically stable atmosphere. The stability of jets arising from compositional pressure gradients requires further study, and this, as well as an analysis of the tropical transient eddies, will be reserved for future work.

Since the pole-to-equator insolation gradient is held fixed in these simulations, the weakening of the meridional temperature gradient as non-diluteness is increased implies that the atmosphere must be carrying heat poleward at a greater rate in the more non-dilute cases. This may seem surprising, given that the atmospheric mass goes down in these simulations as the non-condensible background gas is reduced. However, while total atmospheric mass goes down, the mass of water vapour in the atmosphere rises markedly from experiment P1000 to P0, due to the decrease in vertical lapse rate and the rise of atmospheric relative humidity. This allows increased poleward latent heat transport \( \int_0^p (Lq \nu) dp/g \), leading to the uniform surface temperature in experiment P0. Figure 12 shows the meridional distributions of the shortwave and longwave radiative fluxes at the top of the model together with \((E-P)\) for the pure steam case. The outgoing longwave radiation is essentially independent of latitude in this case. \((E-P)\) has the right shape and magnitude (when scaled by latent heat) to balance the radiative imbalance, verifying that, though thin, the latent heat of the atmosphere allows it to nonetheless transport energy efficiently. This mechanism breaks down for atmospheres where the temperature can only produce an extremely low vapour pressure, as is the case for the local condensing SO2 atmosphere of Io. The analogous local rock vapour atmospheres discussed in [5] are not especially thin, nor is the latent heat of rock vapour condensation notably small; the breakdown of the barotropic global atmosphere behaviour in this case is probably due to the high rate of cooling of extremely hot atmospheres.

(d) Saturation dynamics

The relative humidity of an air parcel is the ratio of the partial pressure of the condensible substance in that air parcel to the saturation vapour pressure corresponding to the temperature of the air parcel.

The relative humidity distribution affects the mass of water vapour in the atmosphere and therefore the meridional heat transport. Further, when the condensible is a greenhouse gas (as in
the case of water) it has a strong impact on the radiation budget of the planet. For the Earth’s
troposphere, how the relative humidity is distributed and how this distribution changes in a
warming world are key questions involved in understanding the feedbacks that determine the
sensitivity of climate to changes in radiative forcing. This would be equally true for other planets
for which the condensable substances have a significant greenhouse effect.

A paradigm of non-local large-scale control of tropospheric humidity has long been proposed
for understanding the relative humidity distribution in the Earth’s atmosphere, known as the
advection–condensation model [27,37]. This model makes use of the property that the mixing
ratio of the condensable in an air parcel is conserved along any segment of a trajectory which does
not encounter conditions where it becomes saturated and loses water by precipitation. Hence the
relative humidity of the air parcel at its destination is the ratio of the saturation molar mixing
ratio \( r_{\text{sat}} \) of water vapour at the position of the last saturation to that at the destination, and the
relative humidity at the final position has no sensitivity to the air parcel’s history at times earlier
than the last saturation. This is an idealized model of relative humidity, as unsaturated air parcels
can gain moisture by evaporation of precipitation or mixing with neighbouring moist parcels,
or lose it by mixing with neighbouring dry parcels; however, the advection–condensation model
has been found to have considerable quantitative explanatory value. In terms of equations, the
last-saturation model giving the relative humidity at position \( x \) can be expressed as

\[
\text{RH}(x) \equiv \frac{p_c(x)}{p_{\text{sat}}(x)} = \frac{r_c(x)}{r_{\text{sat}}(x)} = \frac{p_{\text{sat}}(x_{\text{last}})}{p_{\text{sat}}(x)} \frac{p_a(x)}{p_a(x_{\text{last}})},
\]

where \( r_c \equiv p_c/p_a \) is the molar mixing ratio of the condensable, \( r_{\text{sat}} \) its value at saturation,
\( p_{\text{sat}} \) is the saturation vapour pressure and the subscript ‘last’ stands for the position of last
saturation. This model was used to reconstruct relative humidity in the Earth’s subtropics using
a backward Lagrangian trajectory technique, and showed excellent agreement with the Meteosat
satellite observations [37]. The assumption about water mass in an air parcel in the advection–
condensation model is exactly what occurs in our GCM since there is no microphysical cloud
scheme or small-scale unresolved turbulent mixing (apart from numerical diffusion). Therefore,
we can use the concept of last saturation to explain the simulated relative humidity distribution.
The typical situation leading to strong subsaturation is when the air parcel came from a higher,
colder place. In that case, the first ratio at the end of equation (5.1) is very small, because of
the exponential dependence of saturation vapour pressure on temperature; the second ratio is
greater than unity because of the subsidence and compression of the air parcel, but it is invariably
overwhelmed by the exponentially small first term.

Figure 13 shows the cumulative distribution of the relative humidity for the four simulations.
Results are shown on two different \( \sigma \) surfaces: one near the mid-troposphere (\( \sigma = 0.51 \)) and the
other in the upper atmosphere (\( \sigma = 0.12 \)). First, because the saturation mixing ratio decreases with
height, the driest air parcel in the troposphere usually forms in the subtropics and is last saturated
at the coldest location in the troposphere–tropopause at the equator. We can roughly estimate the
minimum relative humidity in experiment P1000 by the advection–condensation model. From
the mass steamfunction in figure 11e and the air temperature in figure 10a, the driest air parcel
should be last saturated near 150 hPa with the temperature of 235.4 K. Since the subtropics also
satisfy the W TG approximation, the temperature at 510 hPa can be computed by the moist adiabat,
which is 283.4 K. Then the estimated relative humidity given by equation (5.1) is 7.0\%, and very
close to the minimum value in the simulation (the left-endpoint of the red curve in figure 13a).
Second, figure 13a,b shows a general trend that the troposphere becomes more saturated as the
water vapour concentration rises. This is again related to the decrease in the vertical lapse rate
\( (d \ln T/d \ln p) \), which leads to a decrease in the vertical relative change of saturation mixing ratio
\( (dr_{\text{sat}}/dp) \) and a small expansion of the troposphere (figure 10a–c). Although the latter one tends
to dry the upper troposphere, the former one wins the competition.

The role of the last-saturation statistic changes markedly, however, as the pure-steam limit is
approached. For a nearly pure-steam atmosphere, \( p_{\text{sat}}(x_{\text{last}}) \approx p(x_{\text{last}}) \) and since \( p_a/p_c \) is conserved
along the non-condensing trajectory \( p_a(x_{\text{last}})/p_c(x_{\text{last}}) = p_a(x)/p_c(x) \), which in the nearly pure steam
Figure 13. Cumulative distribution function of relative humidity in experiments P1000 (red), P30 (yellow), P5 (green), P0 (blue) on the $\sigma = 0.51$ (a), 0.12 (b) surfaces. The data samples are taken from a 100-day integration and collected once per day.

limit implies $p_a(x)/p_a(x_{\text{last}}) \approx p(x)/p(x_{\text{last}})$. Plugging this into the last equality in equation (5.1) then implies

$$\text{RH}(x) = \frac{p(x)}{p_{\text{sat}}(x)}.$$  

(5.2)

This depends only on the local temperature and pressure where the parcel lands. It is independent of the parcel’s history, except insofar as that history affects the final temperature of the parcel. In contrast with the more dilute cases, subsaturation cannot be created by ‘bringing down’ dry air from aloft. It can only create subsaturation by heating up an air parcel, either by adiabatic compression or net radiative heating. In our simulation, there is no net radiative heating internal to the atmosphere, but in principle, subsaturated air could still be produced by subsiding motions that are fast enough to overcome radiative cooling. This does not happen to any significant extent in our pure steam simulation (the two blue lines in figure 13a,b), and the atmosphere to all intents and purposes becomes saturated everywhere except in the very thin stratosphere (barely visible in the figure) where radiative heating warms the atmosphere to temperatures greater than the dew point.

The upper tropospheric relative humidity (UTRH) can vary the pressure of the radiating level (the optical thickness between the radiating level and the top of the atmosphere is approximately unity for an optically thick grey atmosphere), and therefore the OLR. It is not easy to show the change of the relative humidity above the radiating level directly in the simulations listed in table 3. Here we develop another experiment and simulate a runaway greenhouse atmosphere to study the change of the UTRH as the atmosphere becomes non-dilute and the radiative effect due to this change. We use the temperature, humidity and wind fields on day 3000 of the experiment P1000 as the initial condition and trigger a runaway greenhouse by raising the global mean insolation to 450 W m$^{-2}$. The value is well above the threshold of one-dimensional runaway greenhouse assuming a relative humidity of 45% in our grey radiation scheme. We plot the OLR as a function of $T_s$ with both quantities averaged in the tropics in figure 14b. Owing to the WTG approximation, the comparison between the modelling result and the one-dimensional reference curves corresponding to various relative humidities could roughly$^4$ give the degree of saturation averaged near the tropical radiating level. The relative humidity first stays constant at 45% until the $T_s$ reaches 315 K, and then it continues to rise towards unity as the planet warms. Another

$^4$The relationship between the OLR and the water path is not linear.
Figure 14. (a) Time evolution of the tropical mean $T_s$ (averages are taken within 30° of latitude) in the runaway greenhouse experiment with global mean insolation of 450 W m$^{-2}$. (b) OLR dependence on $T_s$ in tropics. The black curve shows results for the idealized three-dimensional simulation, and grey curves show results for one-dimensional radiative–convective simulations. The one-dimensional model assumes a moist adiabat and uses various values of relative humidity in the one-dimensional radiative transfer.

idealized simulation on the three-dimensional runaway greenhouse grey atmosphere also shows similar trend of the UTRH (fig. 7 in [34]). Recently, Leconte et al. [38] conducted a study of the runaway greenhouse in an idealized three-dimensional GCM with a real-gas radiation scheme. This new simulation showed a decrease in UTRH before runaway greenhouse occurs ($T_s \approx 320$ K, Extended Data fig. 3b in [38]), probably because of the emergence of a cold tropopause owing to real-gas radiation effects. However, when the surface temperature continues to increase and the runaway greenhouse atmosphere becomes non-dilute, the UTRH should rise again and approach unity according to our discussion regarding $d r_{sat}/dp$ above. This effect is not seen in [38], but some indication of this behaviour is found in the simulation of the same problem in [39], which also edges into the non-dilute regime.

This increase in UTRH leads to an interesting question about multiple equilibria in the real runaway greenhouse atmosphere. Assuming constant planetary albedo that does not change with $T_s$, for a pure water-vapour atmosphere, there is only one stable equilibrium state when the net absorbed stellar flux ($S_{abs}$) is less than the Komabayashi–Ingersol limit of the water vapour atmosphere ($F_{KI} \approx 282$ W m$^{-2}$), and no equilibrium state when $S_{abs} > F_{KI}$. For the Earth’s atmosphere, the 1000 hPa of non-condensible components not only dilutes the atmosphere, but also leads to the sub-saturation of the upper troposphere and therefore increases the maximum amount of energy the planet could emit into space ($F_{max} \sim 320$ W m$^{-2}$ shown in Extended Data...
fig. 3b in [38]). Hence, two equilibrium states exist when $F_{KI} < S_{abs} < F_{max}$: one is stable and another unstable. In a real water-vapour atmosphere, the planetary albedo depends on $T_s$ as well. Leconte et al. [38] show a downward trend of the planetary albedo in a dilute atmosphere as the planet warms. For a non-dilute atmosphere, the planetary albedo is primarily determined by the Mie scattering of water clouds and Rayleigh scattering and absorption of water molecules. The latter effect can be easily computed, but the former one is not for we still know little about the cloud microphysics when the atmosphere is non-dilute. If the planetary albedo is a strongly nonlinear function of $T_s$, then more equilibria (possibly stable) may exist in the non-dilute atmosphere. In fact, when applying the relation between the planetary albedo and $T_s$ estimated in a one-dimensional model (fig. 3b in [40]), there would be another stable equilibrium state with $T_s \sim 400$ K under our current insolation. Goldblatt [41] carried out a similar analysis and showed both a cold ($270 \leq T_s \leq 290$ K) and hot ($350 \leq T_s \leq 550$ K) stable climate state for a pure water atmosphere.

6. Discussion

Given the vast amount of energy stored as latent heat in non-dilute atmospheres, one might expect them to exhibit violent behaviour, with extreme convective storms perhaps reducing pressures locally to a near vacuum as massive proportions of the atmosphere rain out. In fact, we have found strongly non-dilute atmospheres to be rather quiescent places, with largely barotropic dynamics, weak temperature gradients, sluggish circulations, and rather gentle laminar ascent in convective regions instead of the boiling cumulus towers familiar from the Earth’s tropics. All of these features can be understood in terms of well-established thermodynamic and GFD principles applied in a novel way. Ironically, it may be difficult or impossible for hurricanes to form in highly non-dilute atmospheres. The quiescent nature of non-dilute atmospheres is already suggested by the example of Titan, which has rather weak condensationally driven activity in its troposphere despite the very considerable amount of energy stored in the form of latent heat of condensible methane—vast amounts of energy are there, but the dynamics cannot get at it. Titan, however, is weakly illuminated and slowly rotating, which may also play a role in its quiescent (though nonetheless interesting) dynamics. We have shown that similar behaviour emerges even in rapidly rotating cases with Earth-like instellation.

An important result obtained from our simulations is that atmospheres become increasingly saturated throughout a deepening layer as they become more non-dilute. This has critical implications for the conditions which support a runaway greenhouse for water vapour or other condensible greenhouse gases, as dilute atmospheres can be inhibited from entering into a runaway by subsaturation. The increasing saturation with temperature we have found also confirms earlier speculations that the feedback of increasing relative humidity can potentially lead to multiple equilibria, in which atmospheres can have a metastable non-runaway state and a hot runaway state for the same instellation conditions (though our simulations do not themselves exhibit this multiplicity). An important implication of our results on saturation is that a substantial inventory of non-condensing background gas helps to protect a planet against a runaway greenhouse, through allowing significant subsaturation. This effect is of interest not just for water oceans, but also for the preservation of CO2 oceans, which are of current interest as a possible alternative life-supporting environment [42].

The tendency towards saturation should also make clouds more prevalent in non-dilute atmospheres, as clouds form in saturated or supersaturated air—though the weakness of vertical motions in non-dilute atmospheres could work against this expectation.

Though in some sense sluggish, non-dilute atmospheres nonetheless exhibit a variety of novel and challenging dynamical phenomena. Angular momentum carried by precipitation allows global or near-global surface westerlies to prevail. One can raise related questions about the way non-dilute precipitation affects potential vorticity dynamics. Compositionally induced pressure gradients allow strong baroclinic jets even when horizontal temperature gradients are weak, but these jets appear to be stable against baroclinic instability. The width of the weak non-dilute
Hadley circulations remains to be understood, and the tropics of non-dilute atmospheres exhibit a variety of large-scale transient convective clusters whose dynamics remain to be elucidated; they are likely to have a strong influence on the cloud patterns of non-dilute atmospheres.

This paper also serves to introduce a new tool—exo-FMS—we have developed for simulation of the three-dimensional climate dynamics of quite general exoplanet atmospheres. This model will be put to further use in future work, and it is our intention to develop it into an open-source platform for planetary circulation modelling. Future studies will include the examination of non-dilute circulations on tide-locked planets, study of planets where most of the instellation is deposited in the atmosphere rather than at a distinct surface, and characterization of a range of possible cloud effects. More generally, there is considerable work that needs to be done in order to incorporate microphysical effects into the modelling of non-dilute atmospheres. In the absence of suitable cloud condensation nuclei, atmospheres may become highly supersaturated before condensate forms, and this is bound to have dynamical effects. Further, the effect of retained condensate in the case where condensate particles remain small can significantly affect buoyancy and inhibit convection. The microphysics governing precipitation and re-evaporation also affect the vertical transport of chemical species in a planetary atmosphere, and therefore affect the vertical structure of atmospheric composition.

Few of the dynamical aspects we have discussed are currently accessible to detailed observational study. Observational techniques, however, continue to advance at a breathtaking pace. This will expand the range of theories that can be tested. Inevitably, such advances will also turn up additional surprises. We should be prepared to think about them, and that will require climate dynamics thinking well outside the terrestrial box. Non-dilute atmospheres are but one example of the class of novel atmospheres that will need to be considered.

Data accessibility. All data used to support conclusions can be found in the manuscript, and the electronic supplementary material. The electronic supplementary material contains technical details that may be of use to readers attempting to reproduce our results using their own models.
