In our derivation of the second law of thermodynamics from the relation of adiabatic accessibility of equilibrium states, we stressed the importance of being able to scale a system’s size without changing its intrinsic properties. This leaves open the question of defining the entropy of macroscopic, but unscalable systems, such as gravitating bodies or systems where surface effects are important. We show here how the problem can be overcome, in principle, with the aid of an ‘entropy meter’. An entropy meter can also be used to determine entropy functions for non-equilibrium states and mesoscopic systems.

1. Introduction

In our previous work [1–6] (see also [7]), we showed how to define the entropy of ‘normal systems’ in equilibrium that are scalable, and showed that this entropy is essentially unique. It was derived without introducing the concepts of heat or temperature, and was based solely on the notion of adiabatic accessibility and comparability of states with respect to this relation. In a word, the entropy of a system was defined by letting scaled copies of a system act on each other via an adiabatic process. This procedure is obviously not appropriate for systems that cannot be divided into parts that have intrinsic properties identical to those of a larger system.

Here, instead, we propose to use a normal system (defined at the end of §2), for which the entropy has already been established, as an ‘entropy meter’ by letting it act, in an adiabatic process, on a system whose entropy is to be determined. The standard way
to measure entropy, as illustrated, for example, by the ‘entropy meter’ in [8, pp. 35–36], presupposes that the system to be measured has a well-defined entropy and, more importantly, assumes that it has a definite absolute temperature uniformly throughout the system. The definition of temperature in a non-normal system is not at all obvious. Our entropy meter assumes none of these things and is based, instead, on the relation of adiabatic accessibility, as in [2].

Giles’s work [9] is a precursor of ours, as we stated in [2], but his definition of entropy for general systems, while similar in spirit, is not the same as the one described here or in [6]. Another step in the direction of a definition of entropy for general systems has been taken by Badiali & El Kaabouchi (Badiali JP, El Kaabouchi A. Entropy in non-traditional systems, private communication, 2013) who consider systems having scaling properties with fractional exponents and satisfying modifications of the axioms of [2].

Comment: the word ‘meter’ as used in our paper is a bit unusual in the sense that the measurement involves changes in the system to be measured, whereas a ‘meter’ is normally thought to be best if it interacts least. However, any physical measurement of entropy, for any kind of system, requires a state change, for example, integration of $\delta Q/T$. Practically speaking, changing the state of the sun is out of bounds, but there are many human-sized, non-scalable and non-equilibrium systems that need to be considered, for example, systems with sizeable surface contributions to the entropy.

Our motivation is to identify entropy as a quantity that allows us to decide which states can be transformed, adiabatically, into which other states. Here, we recall that an adiabatic process for us is a ‘work process’ [10,11] and does not require adiabatic enclosures or slow motion or any such constraints. We do not want to introduce heat or temperature ab initio, and thus require only that changes in an adiabatic process leave no mark on the universe other than the raising/lowering of a weight or stretching/compressing a spring.

Our definition of entropy is presented in the next three sections for three classes of systems. In each section, we define two entropy functions, denoted by $S_-$ and $S_+$, which are determined by a double variational principle. The definitions of these functions are illustrated by figures 1–3. An essentially unique entropy characterizing the relation $<$ exists if and only if these two functions are equal and this, in turn, is equivalent to the condition of comparability of the states under consideration. This comparability, which is a highly non-trivial property, was established for normal, scalable systems (called ‘simple systems’) in [2] by using certain structural properties of the states of normal systems that are physically motivated, but go way beyond other much simpler and almost self-evident order-theoretical assumptions about the relation $<$ that were the only properties used in the first part of our paper. In [6], we argued that comparability can generally not be expected to hold for non-equilibrium states. In §4, where we use entropy meters to construct entropy for general, non-scalable systems, we assume comparability, but show also that should comparability not hold, the two different functions $S_{\pm}$ nevertheless still encode physically useful information about the relation of adiabatic accessibility.

Because our definition of entropy (or entropies) uses only the relation $<$ and its properties, it can be used in any situation where such a relation is given. Hence, our definitions are, in principle, also applicable to mesoscopic systems and to non-equilibrium states. For the latter, it provides an alternative route to the method of [6] which is sketched in §3. Concerning mesoscopic systems, it can be expected that the relation $<$, and hence the second law, becomes increasingly ‘fuzzy’ when the size of the system approaches atomic dimensions, and the possibility of quantum entanglement between a system and its surroundings has to be taken into account [12–14]. In such extreme situations, our framework will eventually cease to apply, but there is still a wide intermediate range of sizes above atomic scales where a non-extensive entropy in the sense of this paper may be a useful concept.

A final point to mention is that direct applications of the formulae (2.1)–(2.2), (3.1)–(3.2) or (4.2)–(4.3) may not be the most convenient way to determine entropy, in practice, although we have shown that it is possible in principle. The existence of entropy is still a valuable piece of information, and in the cases when we have shown uniqueness, we can be sure that more conventional methods, based, for example, on measurements of heat capacities, compressibilities,
2. Basic definition of entropy

We start with a very brief outline of our definition of entropy for normal systems in [2]. See [6, section 2] for a concise summary. The set of equilibrium states of a system of a definite amount of matter is denoted by $\Gamma$. It is not necessary to parametrize the points of $\Gamma$ with energy, volume, etc., for our purposes here, although we do so in [2] in order to derive other thermodynamic properties of the system, specifically temperature.

If $X$ and $Y$ are points in two (same or different) state spaces, we write $X < Y$ (read ‘$X$ precedes $Y$’) if it is possible to change $X$ to $Y$ by an adiabatic process in the sense above. We write $X \preceq Y$ (read ‘$X$ strictly precedes $Y$’) if $X < Y$ but not $Y < X$, and we write $X \preceq Y$ (‘$X$ is adiabatically equivalent to $Y$’) if $X < Y$ and $Y < X$.

We say that $X$ and $Y$ are (adiabatically) comparable if $X < Y$ or $Y < X$ holds.

Another needed concept is the composition, or product, of two state spaces $\Gamma_1 \times \Gamma_2$, an element of which is simply a pair of states denoted $(X_1, X_2)$ with $X_i \in \Gamma_i$. We can think of this product space as two macroscopic objects lying side by side on the laboratory table, if they are not too large. Finally, there is the scaling of states by a real number $\lambda$, denoted by $\lambda X$. The physical interpretation (that is, however, not needed for the mathematical proofs) is that extensive state variables such as the amount of substance, energy, volume and other ‘work coordinates’ are multiplied by $\lambda$, whereas intensive quantities such as specific volume, pressure and temperature are unchanged.

Logic requires that we introduce a ‘cancellation law’ into the formalism:

— If $(X_1, X_2) < (X_1, Y_2)$ then $X_2 < Y_2$.

In [2], we proved this from a stability axiom, but we can remark that it is not really necessary to prove it, because the law says that we can go from $X_2$ to $Y_2$ without changing the rest of the universe, which is the definition of $<$ in $\Gamma_2$. (See [2, pp. 22–23] for a further discussion of this point.)

To define the entropy function on $\Gamma$, we pick two reference points $X_0 \preceq X_1$ in $\Gamma$. Suppose $X$ is an arbitrary state with $X_0 < X < X_1$ (If $X < X_0$, or $X_1 < X$, we interchange the roles of $X$ and $X_0$, or $X_1$ and $X$, respectively.) From the assumptions about the relation $<$ in [2], we proved that the following two functions are equal:

$$S_- (X) = \sup \{ \lambda' : ((1 - \lambda') X_0, \lambda' X_1) < X \}$$

(2.1)

and

$$S_+ (X) = \inf \{ \lambda'' : X < ((1 - \lambda'') X_0, \lambda'' X_1) \}.$$  

(2.2)

Moreover, there is a $\lambda X$ such that the sup and inf are attained at $\lambda X$.

\footnote{If $X_1 \preceq X$, then $((1 - \lambda) X_0, \lambda X_1) < X$ has the meaning $\lambda X_1 < ((\lambda - 1) X_0, X)$, and the entropy exceeds 1. Likewise, it means that $(1 - \lambda) X_0 < (-\lambda X_1, X)$ if $X \preceq X_0$. See [2, pp. 27–28].}
This central theorem in [2] provides a definition of entropy by means of a double variational principle. An essential ingredient for the proof that $S_-(X) = S_+(X)$ for all $X$ is the comparison property (CP):

— Any two states in the collection of state spaces $(1 - \lambda)\Gamma \times \lambda\Gamma$ with $0 \leq \lambda \leq 1$ are adiabatically comparable.2

The common value $\lambda_X = S_-(X) = S_+(X)$ is, by definition, the entropy $S(X)$ of $X$.

Definition of a normal system. In our original paper [2], we said that ‘simple systems’ are the building blocks of thermodynamic systems and we used them to prove the CP. In our work on non-equilibrium systems [6], we did not make use of simple systems but we did assume, unstated, a property of such systems. Namely that the range of the entropy is a connected set. That is if $X, Y \in \Gamma$ and $S(X) < S(Y)$ then, for every value $\lambda$ in the interval $[S(X), S(Y)]$, there is a $Z \in \Gamma$ such that $S(Z) = \lambda$. This property will be assumed here as part of the definition of ‘normal systems’. The other assumptions have already been stated, that is, the existence of an essentially unique additive and extensive entropy function that characterizes the relation $<$ on the state space $\Gamma$.

3. Entropy for non-equilibrium states of a normal system

In the paper [6], we discussed the possibility of extending our definition of entropy to non-equilibrium states. The setting was as follows: we assume that the space of non-equilibrium states $\hat{\Gamma}$ contains a subspace of equilibrium states for which an entropy function $S$ can be determined in the manner described above. Moreover, we assume that the relation $<$ extends to $\hat{\Gamma}$ and ask for the possible extensions of the entropy from $\Gamma$ to $\hat{\Gamma}$. The concept of scaling and splitting is generally not available for $\hat{\Gamma}$, so that we cannot define the entropy by means of the formulae (2.1) and (2.2). Instead, we made the following assumption:

— For every $X \in \hat{\Gamma}$, there are $X', X'' \in \Gamma$ such that $X' < X < X''$.

We then define two entropies for $X \in \hat{\Gamma}$:

$$S_-(X) = \sup\{S(X') : X' \in \Gamma, X' < X\}$$
\hspace{1cm} (3.1)

and

$$S_+(X) = \inf\{S(X'') : X'' \in \Gamma, X < X''\}.$$ 
\hspace{1cm} (3.2)

These two functions coincide if and only if all states in $\hat{\Gamma}$ are adiabatically comparable; in that case, an essentially unique entropy $S = S_- = S_+$ characterizes the relation $<$ on $\hat{\Gamma}$ in the sense that $X < Y$ if and only if $S(X) \leq S(Y)$. Although comparability for equilibrium states is provable from plausible physical assumptions, however, it is highly implausible that it holds generally for non-equilibrium states apart from special cases, for example, when there is local equilibrium. (See the discussion in [6, section 3(c)].) The functions $S_-$ and $S_+$ contain useful information, nevertheless, because both are monotone with respect to $<$ and every function with that property lies between $S_-$ and $S_+$.

2For $\lambda = 0$ or 1, the space is simply $\Gamma$, by definition.
Figure 2. The picture illustrates the definition of the entropies $S_-$ and $S_+$ for non-equilibrium states of a normal system, cf. equations (3.1) and (3.2). The space of non-equilibrium states is denoted by $\hat{\Gamma}$, whereas $\Gamma$ is the subset of equilibrium states. (Online version in colour.)

4. General entropy definition for non-extensive systems

Our entropy meter is a normal state space $\Gamma_0$ consisting of equilibrium states, as in §2, with an entropy function $S$ characterizing the relation $\prec$ on this space and its scaled products. Suppose $\prec$ is also defined on another state space $\Gamma$ as well as on the product of this space and $\Gamma_0$, i.e. the space $\Gamma \times \Gamma_0$. On such product states, the relation $\prec$ is assumed to satisfy only some of the assumptions that a normal space would satisfy. In the notation of [2], these are

- (A1) Reflexivity: $X \preceq X$
- (A2) Transitivity: $X \prec Y$ and $Y \prec Z$ implies $X \prec Z$
- (A3) Consistency: if $X \prec X'$ and $Y \prec Y'$, then $(X, Y) \prec (X', Y')$.
- (A6) Stability with respect to $\Gamma_0$: If $(X, \varepsilon Z_0) \prec (Y, \varepsilon Z_1)$ with $Z_0, Z_1 \in \Gamma_0$ and a sequence of $\varepsilon$ tending to zero, then $X \prec Y$.

Note that A4 (scaling) and A5 (splitting and recombination) are not required for (product) states involving $\Gamma$, because the operation of scaling need not be defined on $\Gamma$. We now pick two reference states, $Z_0 \in \Gamma_0$ and $X_1 \in \Gamma$, and make the following additional assumption.

- (B1) For every $X \in \Gamma$, there are $Z', Z'' \in \Gamma_0$ such that

$$\left( X_1, Z' \right) \prec \left( X, Z_0 \right) \prec \left( X_1, Z'' \right).$$

(4.1)

We use $\Gamma_0$ as an ‘entropy meter’ to define two functions on $\Gamma$:

$$S_-(X) = \sup \{ S(Z') : (X, Z_0) \prec (X, Z') \}$$

(4.2)

and

$$S_+(X) = \inf \{ S(Z'') : (X, Z_0) \prec (X_1, Z'') \}.$$  

(4.3)

If $S_+(X) = S_-(X)$, then we denote the common value by $S(X)$. Theorem 4.1 shows that this is the case under a suitable hypothesis and that $S$ has the required properties of an entropy function.

Remarks.

1. The definition of $S_{\pm}$ is similar the one used in the proof of theorem 2.5 in [2] for the calibration of the multiplicative entropy constants in products of ‘simple systems’.
2. The functions defined in (4.2) and (4.3) give a definition of the upper/lower entropies of non-equilibrium states different from the definition given in [6], cf. equations (3.1) and (3.2). Numerically, they are identical up to additive constants, however, when both definitions apply.
Figure 3. The processes used to define entropy for a system $\Gamma$ with the aid of an entropy meter, $\Gamma_0$. Figure (a) illustrates the definition of $S_-$ (equation (4.2)), figure (b) that of $S_+$ (equation (4.3)). (Online version in colour.)

3. Assumption (B1) may appear to be rather strong, because when the $\Gamma$ system is large compared with the $\Gamma_0$ entropy meter, then (4.1) essentially says that the small system can move the large one from $X_1$ to $X$ and from $X$ to $X_1$. In such a case, this can be expected to hold only if $X$ and $X_1$ are close together. To overcome this difficulty, we introduce ‘charts’, as we do in differential geometry. The state space $\Gamma$ is broken into small, overlapping subregions and our theorem 4.1 (with the same $\Gamma_0$ if desired) is applied to each subregion. The saving point is that the entropy in each subregion is unique up to an arbitrary additive constant, which means that the entropies in two overlapping subregions must agree up to a constant.

Can we fix an additive constant in each subregion so that every overlap region has the same entropy? In principle, one could imagine an inconsistency in the additive constants as we go along a chain of overlapping subregions. A way to negate this possibility is to note that if one can define a global entropy function then the mismatch along a closed loop cannot happen. A global entropy can be constructed, in principle, however, by starting with a sufficiently large-scale copy of $\Gamma_0$, which might not be practical physically, but which exists, in principle, because $\Gamma_0$ is supposed to be scalable. With this large copy, only one chart is needed and, therefore, the entropy exists globally.

Our main new result is the following, which shows that $\Gamma_0$ can be used to determine, essentially uniquely, an entropy function on the non-extensive system $\Gamma$. More generally, we can consider a product $\Gamma_1 \times \Gamma_2 \times \cdots \times \Gamma_n$ of such non-extensive systems.

**Theorem 4.1.** Let us assume, in addition to the conditions above,

— (B2) Comparability: every state in any multiple-product of the spaces under consideration is comparable to every other state in the same multiple-product space.

Then, $S_- = S_+$ and this function, denoted again by $S$, is an entropy on $\Gamma$ in the sense that $X < Y$ if and only of $S(X) \leq S(Y)$. A change of $Z_0$ or $X_1$ amounts to a change of $S$ by an additive constant.

The entropy is additive in the sense that the function defined by $S(X, Y) = S(X) + S(Y)$, with $X, Y \in \Gamma$, is an entropy on $\Gamma \times \Gamma$, and likewise $S(X, Z) = S(X) + S(Z)$ with $X \in \Gamma$, $Z \in \Gamma_0$, is an entropy on $\Gamma \times \Gamma_0$. More generally, the entropy is additive on a product of systems $\Gamma_1 \times \Gamma_2 \times \cdots \times \Gamma_n$, in the sense that $S(X_1) + S(X_2) + \cdots + S(X_n)$ is an entropy on this space.

Finally, the entropy is determined uniquely by these properties, up to an arbitrary additive constant. Its unit of entropy is that of $\Gamma_0$.

**Proof.** Step 1: the proof that $S_- = S_+ = S$, and that $S$ is an entropy is similar to the proof of proposition 3.1 in [6]. We start by proving that for every $X \in \Gamma$ there is a $Z_X \in \Gamma_0$ such that

$$(X, Z_0) \sim (X_1, Z_X). \quad (4.4)$$
To prove (4.4), we use the stability assumption (A6) for \( \Gamma_0 \) to show that the sup and inf in the definitions (4.2) and (4.3) are attained, that is there are \( Z'_X \) and \( Z''_X \) in \( \Gamma_0 \) such that \( S(\cdot) = S(Z'_X) \) and \( S(\cdot) = S(Z''_X) \).

Indeed, because \( S(Z') \leq S(Z'') \), if \( Z' \) and \( Z'' \) are as in (4.1), and \( \Gamma_0 \) is a normal system, there is a \( Z'_X \in \Gamma_0 \) such that \( S(X) = S(Z'_X) \). We claim that \( (X'_1, Z'_X) < (X, Z_0) \). By definition of \( S(X) \), for every \( \varepsilon > 0 \), there is a \( Z'_X \in \Gamma_0 \) such that \( (X'_1, Z'_X) < (X, Z_0) \) and \( 0 \leq S(Z'_X) - S(Z'_X) \leq \varepsilon \). Now, pick two states \( Z_1, Z_2 \in \Gamma_0 \) with \( Z_1 - Z_2 > 0 \). Then, there is a \( \delta(e) \to 0 \) such that \( S(Z'_X) = S(Z'_X) + \delta(e)S(Z_1) \) which means that \( (Z'_X, \delta(e)Z_1) \approx (Z'_X, \delta(e)Z_2) \). This, in turn, implies \( (X', \delta(e)Z_1) \approx (X, \delta(e)Z_2) \) and hence \( (X'_1, Z'_X) < (X, Z_0) \) by stability. The existence of \( Z'_X \) with \( S(\cdot) = S(Z'_X) \) is shown in the same way. This establishes the existence of a maximizer in (4.2) and a minimizer in (4.3).

If \( S(X) < S(\cdot) \), then there is, by the definition of normal systems, a \( \tilde{Z} \in \Gamma_0 \) with \( S(\tilde{Z}) < S(\tilde{Z}) \). (It is here that we use the assumption of connectivity of the range of \( S \).) By comparability, we have either \( (X, \tilde{Z}) < (X, Z_0) \), which would contradict \( S(X) = S(Z'_X) \) or else we have \( (X, Z_0) < (X, \tilde{Z}) \), which would contradict \( S(\cdot) = S(Z'_X) \). Hence, \( S(X) = S(\cdot) = S(X) \).

Either \( Z'_X \) or \( Z''_X \) can be taken as \( Z_X \). This establishes (4.4).

Now, we take \( X, Y \in \Gamma \). We have that both \( (X, Z_0) \leq (X, Z_X) \) and \( (Y, Z_0) \leq (X, Z_Y) \), which implies the following equivalences:

\[
X < Y \text{ if and only if } Z_X < Z_Y \text{ if and only if } S(X) = S(\cdot) \leq S(\cdot) = S(Y). \tag{4.5}
\]

Therefore, \( S \) is an entropy on \( \Gamma \).

**Step 2:** if \( \tilde{Z}_0 \) and \( \tilde{X}_1 \) are different reference points, then, likewise, there is a \( \tilde{Z}_X \) such that

\[
(X, \tilde{Z}_0) \approx (\tilde{X}_1, \tilde{Z}_X), \tag{4.6}
\]

and we denote the corresponding entropy by \( \tilde{S}(X) = S(\tilde{Z}_X) \). Now, (4.4) and (4.6) imply

\[
(X_1, Z_X, \tilde{Z}_0) \approx (X, Z_0, \tilde{Z}_0) \approx (\tilde{X}_1, \tilde{Z}_X, Z_0) \approx (X_1, Z_X, \tilde{Z}_X). \tag{4.7}
\]

In the three steps we have used, successively, \( (X_1, Z_X) \approx (X, Z_0) \), \( (X, \tilde{Z}_0) \approx (\tilde{X}_1, \tilde{Z}_X) \) and \( (\tilde{X}_1, Z_0) \approx (X_1, Z_X) \). By the cancellation law, (4.7) implies

\[
(Z_X, \tilde{Z}_0) \approx (Z_X, \tilde{Z}_X). \tag{4.8}
\]

which, because \( \Gamma_0 \) is a normal state space with an additive entropy, is equivalent to

\[
S(X) + S(\tilde{Z}_0) = S(\tilde{X}_1) + \tilde{S}(X). \tag{4.9}
\]

**Step 3:** the proof that \( S(X) + S(\cdot) \) is an entropy on \( \Gamma \times \Gamma \) goes as follows: \( (X, Y) < (X', Y') \) is (by A3 and the cancellation property) equivalent to \( (X, Y, Z_0, Z_0) < (X', Y', Z_0, Z_0) \), which, in turn, is equivalent to \( (X_1, Z_X, Z_Y) < (X'_1, Z'_X, Z'_Y) \). By cancellation, this is equivalent to \( (Z_X, Z_Y) < (Z'_X, Z'_Y) \), and by additivity of the entropy on \( \Gamma_0 \times \Gamma_0 \), and by the definition of the entropies on \( \Gamma \), this holds if and only if \( S(X) + S(Y) \leq S(X') + S(Y') \). The additivity of the entropy on \( \Gamma \times \Gamma_0 \) as well as on \( \Gamma_1 \times \cdots \times \Gamma_n \) is shown in the same way.

**Step 4:** to show that any additive entropy function \( \tilde{S} \) on \( \Gamma \times \Gamma_0 \) that satisfies the condition \( \tilde{S}(X, Z) = \tilde{S}(X) + S(Z) \) necessarily coincides with \( S(X) + S(Z) \) up to an additive constant, we start with (4.4), which implies \( \tilde{S}(X) + S(Z_0) = \tilde{S}(X_1) + S(Z_X) \). However, \( S(Z_X) = S(X) \), as we proved, and, therefore, \( \tilde{S}(X) = S(X) + (S(X_1) - S(Z_0)) \), as required.

Because the CP (B2) is highly non-trivial and cannot be expected to hold generally for non-equilibrium states, as we discussed in [6], it is important to know what can be said without it. If (B2) does not hold the functions \( S_\pm \) defined in equations (2.1) and (2.2) will generally depend in a non-trivial way on the choice of the reference points, and they need not be additive. They will,
nevertheless, share some useful properties with the functions defined by (3.1) and (3.2). The following proposition is the analogue of proposition 3.1 in [6]:

**Proposition 4.2.** The functions $S_\pm$ defined in equations (2.1), (2.2) have the following properties, which do not depend on (B2):

1. $X < Y$ implies $S_-(X) \leq S_-(Y)$ and $S_+(X) \leq S_+(Y)$.
2. If $S_+(X) \leq S_-(Y)$, then $X < Y$.
3. If we take $(X_1, X_1) \in \Gamma \times \Gamma$ and $Z_0 \times Z_0 \in \Gamma_0 \times \Gamma_0$ as reference points for defining $S_\pm$ on $\Gamma \times \Gamma$ with $\Gamma_0 \times \Gamma_0$ as entropy meter, then $S_-$ is superadditive and $S_+$ is subadditive under composition, i.e.

   \[
   S_-(X) + S_-(Y) \leq S_-(X, Y) \leq S_+(X, Y) \leq S_+(X, Y) + S_+(Y).
   \]  

   (4.10)

4. If we take $(X_1, Z_0)$ and $Z_0$ as reference points for the definitions of $S_\pm$ on $\Gamma \times \Gamma_0$, with $\Gamma_0$ as entropy meter, then the functions $S_\pm$ on this space satisfy

   \[
   S_\pm(X, Z_0) = S_\pm(X) \quad \text{and} \quad S_\pm(X_1, Z) = S(Z).
   \]  

   (4.11)

If $\hat{S}$ is any other monotone function with respect to the relation $\prec$ on $\Gamma \times \Gamma_0$, such that $\hat{S}(X_1, Z) = S(Z)$, then

\[
S_-(X) \leq \hat{S}(X, Z_0) \leq S_+(X) \quad \text{for all } X \in \Gamma.
\]  

(4.12)

**Proof.** Part (1). If $X < Y$, then, by the definition of $Z'(X)$ (cf. step 1 of the proof of theorem 4.1), we have $S_-(X) = S(Z'(X))$ and $(X_1, X') < (X, Z_0) < (Y, Z_0)$. By the definition of $S_-(Y)$, this implies $S_-(X) = S(Z'(X)) \leq S_-(Y)$. In the same way, one proves $S_+(X) \leq S_+(Y)$ by using the property of $Z''(X)$.

Part (2). If $S_+(X) \leq S_-(Y)$, then $S(Z'(X)) \leq S(Z'(Y))$ which implies $Z'(X) < Z'(Y)$. Hence, $(X, Z_0) < (X_1, Z') < (X_1, Z'_0) < (Y, Z_0)$, and thus $X < Y$, by cancellation.

Part (3). We have $(X_1, X_1, Z_0') < (X, Y, Z_0, Z_0) < (X_1, X_1, Z_0', Z_0')$. By the definition of $S_\pm$ on $\Gamma \times \Gamma$, this implies $S(Z'(X), Z'(Y)) \leq S_-(X, Y) \leq S_+(X, Y) \leq S(Z'(X), Z'(Y))$, and the statement follows from the additivity of $S$ on $\Gamma_0 \times \Gamma_0$.

Part (4). By definition,

\[
S_-(X, Z) = \sup\{S(Z') : (X_1, Z_0, Z') < (X, Z, Z_0)\} = \sup\{S(Z') : (X_1, Z') < (X, Z)\},
\]  

(4.13)

\[
\{S(Z) : (X_1, Z_0, Z') < (X, Z, Z_0)\} \text{ where the cancellation property has been used for the last equality. In the same way,}
\]

\[
S_+(X, Z) = \inf\{S(Z'') : (X, Z, Z'_0) < (X, Z, Z'_0)\}.
\]  

(4.14)

This immediately implies (4.11).

Now, let $\hat{S}$ be monotone on $\Gamma \times \Gamma_0$ with $\hat{S}(X_1, Z) = S(Z)$. We have $S_-(X) = S(Z'(X))$ with $(X_1, Z'(X)) < (X, Z_0)$. Therefore, $S_-(X) = S(Z'(X)) = \hat{S}(X_1, Z'(X')) \leq \hat{S}(X, Z_0)$.

In the same way, $\hat{S}(X, Z_0) \leq S_+(X)$.

\[ \Box \]

5. Conclusion

We have considered the question of defining entropy for states of systems that do not have the usual property of scalability or of being in equilibrium, especially the former. We do so in the context of our earlier definitions of entropy via the relation of adiabatic accessibility, without introducing heat or temperature as primary concepts. We make no reference to statistical mechanical definitions but only to processes that are physically realizable—in principle, at least.

Our tool is an ‘entropy meter’, consisting of a normal system for which entropy has been firmly established by our previous analysis. By measuring the change in entropy of the meter when it interacts with the system to be measured we can, in favourable cases, define an unambiguous entropy function for states of the observed system. We find that the quantity so defined actually
has the properties expected of entropy, namely that it characterizes the relation of adiabatic accessibility (i.e. one state is accessible from another if and only if its entropy is greater), and is additive under composition of states.

A central concept is comparability of states, which we proved for equilibrium states of normal systems in our earlier work. This property cannot be expected to hold, generally, for non-equilibrium states, as discussed in [6]. We can, however, always define two functions $S_-$ and $S_+$ for systems, which have some of the properties of entropy, and which delimit the range of possible adiabatic processes. It is only for the favourable case $S_- = S_+$ that a true entropy can be proved to exist—as we do here under the condition that comparability holds.
